Bouquet of Spring Flowers.—Extraits de rose et violette, each one pint; extrait d'acacia and essence of rose, each two and a half ounces; attar of bergamot, two drachms; tincture of ambergris, one ounce. Mix, and after ten days, filter.

There are certain *bouquets*, of fine odor, which may be compounded direct from the volatile oils; as an example, there is—

Bouquet de Rondeletia.—Attar of lavender, two ounces; attars of cloves and bergamot, each one ounce; attar of roses, three drachms; tinctures of musk, vanilla, and ambergris, each four ounces; deodorized alcohol, one gallon. Mix, and after a month's repose, filter.

COLOGNE AND OTHER FRAGRANT WATERS.—These preparations are mostly solutions of *bouquets* of essential oils, or extracts, in alcohol, improved by distillation. For common kinds distillation is omitted.

Eau de Cologne—Dorocherau's.—Inodorous alcohol, one gallon; attars of portugal and bergamot, nine drachms; attar of neroli, ten drachms; attar of petit-grain, twelve drachms; attars of lemon, lavender, and rosemary, each one ounce; rose, jasmin, and orange-flower waters, each two ounces. Mix by shaking, and after two weeks' repose distil, and set aside for a year.

Eau de Cologne—Double.—Inodorous alcohol, three gallons; attar of bergamot, twelve ounces; attars of cedrant, lemon, and portugal, each two ounces; attar of lavender, one ounce; attars of neroli and rosemary, each two and a half ounces; attar of thyme, one drachm. Mix, and after a week's repose, distil, and then dilute with orange-flower water until the liquor marks.

Eau de Cologne.—Spirit from grape, sixty over proof, six gallons; attar of neroli petale, three ounces; attar of biggasade, one ounce; attar of rosemary, two ounces; attar of orange peel, five ounces; of citron peel, five ounces; and of bergamot peel, two ounces. Mix with agitation, then allow it to stand for a few days undisturbed, filter and bottle.

Eau de Rondeletia.—French alcohol, one gallon; attar of lavender, two ounces; attars of cloves and bergamot, each one ounce; attar of roses, three drachms; tinctures of musk, vanilla, and ambergris, each four ounces. Mix, and leave to repose for a month, then filter and bottle.

COSMETICS.—The preparations under this head are designed to soften the skin and beautify the complexion. We annex recipes for the more important. The heating medium in the manufacture of them must be either a water or steam bath.

Amandine.—Put into a large marble mortar two ounces gum arabic, and six ounces white honey, triturate, and when the mixture has been rubbed into a thick paste, add three ounces perfectly neutral almond shaving paste. Then continue the trituration until the mixture has become homogeneous. Two pounds of fresh cold-pressed sweet almond oil are next allowed to flow from a can above into the water, but only as rapidly as the workman can incorporate it with the mass; otherwise, if it enters in too large quantities, the blending is imperfect, and the amandine becomes *oily* instead of jelly-like and transparent, as it should be when the manipulation has been skilful. In summer temperatures it will be difficult to effect a combination of all the oil; and, therefore, the flow should be stopped as soon as the mixture becomes bright and assumes a crystalline lustre. The perfume should be mixed with the almond oil, and consists of half a drachm of attar of bitter almonds to every pound of paste. A little attar of rose and bergamot may also be added—about one drachm of each. As soon as finished it must be put in close pots. A small quantity, say a lump of filbert size, gives with warm water a rich lather, which, when rubbed over the face and hands, imparts softness, and prevents chapping. It should be wiped off, while still in lather, with a dry towel.

Camphor Ice.—Melt together over a water-bath, white wax and spermaceti, each one ounce; camphor, two ounces; in sweet almond oil, one pound. Next, triturate in the manner directed for amandine, and allow one pound of rose water to flow in slowly during the operation. Then perfume with attar of rosemary, one drachm.

Crème de Cathay—Farina.—Melt together over a water-bath white wax and spermaceti, each two drachms; then add oil of sweet almonds, four ounces; and mecca balsam, three drachms; next, perfume with rose water, six drachms; and stir until cold.

Glycerin Cream.—This superior cosmetic is the well-known *cold cream*, with glycerin substituted for rose water. Melt together spermaceti, six ounces; and white wax, one ounce; in one pound of sweet almond oil. Then remove from the fire, and stir in PRICE's glycerin, four ounces; and when congealing, perfume with attar of rose, twenty drops. Other attars may be used as desired in place of rose.

Pâte d'Amande au Miel.—Rub together one pound of honey and the yolks of eight eggs; then gradually add sweet almond oil, one pound, during constant trituration; and work in bitter almonds—blanched and ground to meal—eight ounces; finally perfume with attars of bergamot and cloves, each two drachms.

Pomade Rosat—for the lips.—Melt together white wax, two ounces; oil of sweet almonds, four ounces; alkanet, three drachms. Digest for several hours, strain, and add twelve drops of attar of rose.

Crème de Psyché—for the lips.—White wax and spermaceti, each one ounce; oil of sweet almonds, five ounces. Melt together, and pour in mecca balsam, one drachm, and stir until the mass congeals, when add ten grains of powdered acetate of lead.

Lait Virginal.—Orange-flower water, eight ounces; and tincture of benzoin, two drachms. The former is added very slowly to the latter during constant trituration, so as to produce an opalescent milky fluid.

Milk of Roses.—Place over a water-bath, oil soap one ounce; and melt it in five or six ounces of rose-water; then add white wax and spermaceti, one ounce; and continue the heat until they have fused. Next take one pound of blanched almonds, beat them to meal in a clean marble mortar, with three and a half pints of rose-water, admitted portionwise, during the trituration. The emulsion of almonds, thus made, is to be strained without pressure through washed white muslin, and run very slowly into the previously-formed soap-mixture; the whole being blended at the same time by energetic trituration. Towards the end of this operation, two drachms of attar of rose, dissolved in eight ounces inodorous alcohol, is to be let into the mixture very gradually, and in a thin stream, during constant rubbing of the mass. This cautious manipulation is indispensable to the smoothness and perfection of the milk. The last operation is to strain; and after the liquid has had a day's repose, to bottle it.

Piessé's Milk of Cucumber.—Heat two pints juice of cucumbers to boiling, cool and strain; and make into milk, as above directed, with sweet almonds, four ounces; green oil and wax, and curd soap, each half an ounce; alcohol, eight ounces, and essence of cucumber,

four ounces. This latter is made by digesting twenty-eight pounds bruised cucumbers with two pints of alcohol of .837 specific gravity for twenty-four hours; and then distilling off one pint and a half.

Crème de Pistache.—Pistachio nuts, three ounces; green oil, palm soap, wax, and spermaceti, each one ounce; orange-flower water, three and a quarter pints; essence of neroli, twelve ounces; make as directed for the preceding milks.

PREPARATIONS FOR THE HAIR.—In addition to the various kinds of pomades and antique oils already described, there are other special preparations used for promoting the growth, health, and beauty of the hair. Annexed are formulæ for those most esteemed.

Philocomé.—This compound is made without heat. Equal parts of purified beef-marrow, oils of noisettes and sweet almonds are thoroughly mixed by trituration in an agate or marble mortar; and the whole is then perfumed by the addition of a sufficient quantity of a mixture of extracts of rose, acacia, jasmin, orange flower, and tuberose.

Macassar Oil.—Oil of ben, one gallon; oil of noisette, half a gallon; strong alcohol, one quart; attar of rose, two drachms; attar of bergamot, three ounces; attar of portugal, two ounces; and tincture of musk, three ounces; mix together, digest with alkanet root—for color—in a stoppered bottle for a week, then strain and bottle.

Morfit's Hair Tonic.—Scald black tea, two ounces, with one gallon of boiling water; strain, and add three ounces of glycerin; tincture cantharides, half an ounce; and bay rum, one quart. Mix well by shaking, and then perfume.

Shampoo Liquor.—This excellent wash for the hair is made by dissolving carbonate of ammonia, half an ounce, and borax one ounce, in one quart of water, and adding thereto two ounces of glycerin, New England rum three quarts, and one quart of bay rum.

The hair having been moistened with this liquor, it is to be shampooed with the hands until a slight lather is formed; and the latter being then washed out with clear water, leaves the head clean, and the hair moist and glossy.

PREPARATIONS FOR THE TEETH.—These preparations should be compounded of materials, which, while cleaning the teeth without injury to the enamel, will also be antiacid, antiscorbutic, and tonic in their action upon the gums.

Poudre Détersive Dentifrice.—Willow charcoal and white sugar in impalpable powder, each eight ounces; calasay bark in impalpable powder, four ounces; mix thoroughly in a mortar, sift through the finest bolting cloth, and perfume with a mixture of attar of mint, two drachms, attar of cinnamon, one ounce, and tincture of amber, half an ounce.

Camphorated Chalk.—Precipitated carbonate of lime, one pound; powdered orris root, three and a half pounds; powdered camphor, quarter of a pound; reduce the camphor to fine powder by triturating it in a mortar with a little alcohol; then add the other ingredients, and when the mixture is complete, sift through the finest bolting cloth.

Morfit's Dentifrice.—Powdered willow charcoal, four

ounces; cinchona bark and sugar of milk, in powders, each one pound; old transparent soap, in powder, four ounces; mix in a marble mortar, sift through the finest bolting cloth, and perfume with attar of orange flower, one ounce.

Rose Tooth-powder.—Precipitated carbonate of lime, one pound; powdered orris, half a pound; rose pink, two drachms. Mix together; sift and perfume with attar of roses, one drachm; and attar of santal, twenty drops.

Another Dentifrice.—Precipitated carbonate of lime, one pound; powdered borax, half a pound; powdered myrrh, four ounces; powdered orris, four ounces. Mix, and sift through finest bolting cloth.

Opiate Tooth-paste.—Honey, powdered orris, and precipitated carbonate of lime, each half a pound; rose pink, two drachms. Rub into paste with simple sirup, and perfume with attars of cloves, nutmeg, and rose, each half an ounce.

Eau Botot.—Tincture of cedar wood, one pint; tincture of myrrh and rhatany, each four ounces; attar of peppermint, five drops. Mix.

Violet Mouth-wash.—Tincture of orris, essence of rose, and alcohol, each eight ounces; attar of almonds, five drops. Mix.

Cologne Tooth-wash.—Eau de cologne, one quart; tincture of myrrh, four ounces. Mix.

Cachou Aramatisé.—These popular pastilles for perfuming the breath are thus made:—Dissolve three and a half ounces of extract of liquorice in four ounces of water, by the heat of a water-bath, and add of pulverized gum arabic half an ounce, and Bengal catechu, in powder, one ounce. Evaporate to the consistence of an extract, and then mix in, thoroughly, powdered mastic, charcoal, cascarilla, and orris root, each half a drachm. When the mass has been reduced to the proper consistence, it is to be removed from the fire, treated with attar of peppermint, thirty drops; tinctures of ambergris and musk, each five drops; poured out upon an oiled slab, and rolled to a very thin sheet. After cooling, blotting paper is pressed upon it to absorb any adhering oil; and the surfaces are then moistened with water, and covered with silver leaf. When dry it is to be divided into small bits of the size of a fenugree seed.

POWDERS.—Powders for the hair and skin have almost gone out of use. The basis of them is either powdered orris, or fine dry pearl starch. The perfume of the finest kinds is imparted by stratifying starch with fresh flowers, after the manner of enfleurage with fat. The flowers are subsequently separated by sifting. The simple perfumed powders thus obtained, by judicious admixture, form compound or bouquet powders. The tediousness and expense of this process prevent its general employment. The common mode is to scent by the direct addition of extracts or essential oils, or else to mix in powdered fragrant material with the orris or starch. The following formulæ will explain the manufacture of them.

Violet Powder.—Wheat starch, twelve pounds; powdered orris, two pounds. Mix together, and add attar of lemon, half an ounce; attars of bergamot and cloves, each two drachms.

Poudre d'Iris.—Powdered orris root, twelve pounds;

powdered bergamot, peel, and acacia flowers, each eight ounces; powdered cloves, half an ounce. Mix and sift.

Prepared Bran—for the hair.—Powdered wheat bran, one pound; powdered orris, two ounces. Mix and sift.

Poudre Noir—for the hair.—Starch and orris in fine powder, each eight ounces; charcoal and ivory black, in fine powder, each one ounce. Mix and sift.

Poudre Blonde—for the hair.—Finely powdered starch and orris, eight ounces each, as in the preceding, but with yellow ochre for the coloring matter.

Poudre à la Vanille Brune—for the skin or for sachets.—Powdered vanilla, rose leaves, lump storax, benzoin, rhodium, pallsandre and ebony woods, each one pound; powdered cloves, two ounces; powdered musk, two drachms. Mix together with three pounds of starch; sift, and add a few drops of extracts of tuberose and jessamine.

Poudre à l'Éillet Composée—for the skin or sachets.—Powdered rose leaves and orris root, each three pounds; powdered bergamot peel, one pound; powdered cloves and cinnamon, each six ounces; powdered acacia and orange flowers, each eight ounces; starch, three pounds.

ROUGES.—Paints or rouges are the means by which the natural color of the skin may be heightened or changed. They are, however, objectionable preparations, and the use of them extends very little beyond the theatres, where they are employed to produce stage effect.

French White.—This is the mineral talc, or French chalk, finely levigated and bolted. It forms the basis of the most harmless rouges. Perfume is added as may be desired.

Pearl White.—Pure oxide or subnitrate of bismuth in powder. This pigment darkens in atmospheres containing sulphide of hydrogen. One ounce triturated with four ounces of orange-flower water makes liquid white.

Pearl Powder.—Precipitated carbonate of lime, finely bolted and perfumed. The French add oxides of zinc and bismuth, each one ounce to the pound of chalk.

Carmine Rouge.—Finely bolted talc, four ounces; carmine, two drachms. Mix together with a little warm and dilute solution of gum tragacanth. For lighter shades, the proportion of carmine must be increased. For commoner pastes, rose pink replaces the carmine as coloring matter. It may be made into a pomade.

Bloom of Roses.—Powdered carmine of the best quality, two drachms, digested with strong ammonia, four ounces, in a tightly stoppered bottle for two days, at the ordinary temperature of the atmosphere. Then add rose water, one pint, and essence of rose, four ounces. After a week's repose, the upper stratum of clear liquid may be decanted from the subsident matter, and bottled.

Fard Bleu d'Azur.—Talc and ultramarine, finely bolted, equal parts, triturated with a solution of gum tragacanth into a stiff paste.

TOILET SOAPS.—To this class belong the finer kinds of scented soaps, which have emollient properties. They are rarely made direct by the perfumer, the body or basis being a well-selected white soap, subsequently

cleansed and purified. For the choicest grades, the body should be made of a mixture of olive and sweet almond oils, as the fat stock. Lard and beef tallow make the next best stock; and for palm soap a small quantity of bleached palm oil is to be added to them. Cocoa oil and pale yellow rosin saponaceous matters also enter into the composition of certain toilet soaps. These body-soaps may be obtained as wanted from any well-conducted soap factory. To be adapted to the purposes of perfumery they must be perfectly neutral, firm, free from unpleasant odor, and all tendency to *crust* in cold, or *sweat* in damp weather. They should, moreover, give a rich lather without wasting too rapidly in the water. Soaps, generally, in their original condition, are usually deficient in many of those points; and must, for the purposes of perfumery, undergo a refining process, which is as follows:—

The soap, as purchased in bars or blocks, being piled upon the shelf of the rasping machine, is next placed in the hopper, and as the wheel revolves, knives come against the soap and cut it into meal, which falls into the reception box beneath. It is now in a state fit to be melted readily, for which purpose it is transferred to the steam bath before mentioned at pages 669 and 670, and mixed with rose and orange-flower waters, each half a gallon, to every hundred pounds of soap. The steam being let on, and the containing kettle covered, its contents become gradually fluid, and in this state must be stirred with a *crutch*, which is a long stick having the form of an inverted T, until the paste becomes uniformly consistent and smooth throughout. It is then allowed to cool, again melted, but without fragrant water, and crutched as before. When the contents of the vessel comprise several kinds of soap, great care must be observed not to put in all at once, but to add and melt each successively, and to crutch constantly, so as to effect an intimate mixture. When the paste begins to cool, coloring matter as may be desired is then added; and subsequently the perfume, which is reserved to the last, to avoid any unnecessary loss by evaporation from the hot paste. A portion of glycerin might also be added at this stage, with great advantage to the soap, as that liquid imparts an eminent emollient property.

When extracts or bouquets are used, as for scenting the finest kinds of soap, they must be added to the compound in meal, and incorporated with the mass by kneading it with the hands; for the application of heat would impair the delicacy of the odor, as well as occasion loss by its evaporation. In large establishments, this is done by passing the meal repeatedly between marble rollers.

The soap is now ready to be put into the cooling frames, which is a rectangular well made of a series of wooden frames, resting successively one upon the other. In a day or two it is sufficiently hard to be cut into bars and tablets of the size of the sections of each frame, which are fitted by means of a piece of brass wire, which are set up edgewise, and left for several days to dry, and are then barred by means of a wire. The sections or *lifts* of the frame regulate the width of the bars, and the gages adjust their breadth—these latter being made so as to cut bars

or squares of four, six, eight, or any required number to the pound of soap. The bars are further subdivided into tablets, and subjected to pressure for the purpose of imparting solidity, and ornamenting the exterior with some appropriate device, or impressing upon it the maker's name. Moulds for this purpose are shown by Fig. 395, and they may be varied in form and inscription according to taste; but the character of the latter is generally floral or medallion. The press is of ordinary construction, with spiral springs to throw out the soap tablet from the die box as soon as it is pressed. The box is movable, so that the die may be changed at will. In some factories the pressure is more effectually accomplished by means of a steam-hammer, which is made to give three successive blows, directly vertical, to each tablet of soap. Savonettes, or soap balls, are shaped by rotating blocks of soap upon a soap-scoop made of brass with sharp edges.

Fig. 395.

Almond Soap.—This is a very white soap, which, when genuine, is made by the cold process hereinafter described, and from pure oil of sweet almonds. The kind, however, generally met with is made as follows: white curd soap, one hundred pounds, and cocoa-nut oil, fifteen pounds; purified as before directed, and perfumed with a mixture of attar of bitter almonds, one and a half pounds, and attars of cloves and caraway, each eight ounces.

White Windsor Soap.—The genuine old white windsor is made from a body of which a mixture of lard and olive oil is the fat stock; and attars of caraway, lavender, and rosemary, constitute the perfume. The modern windsor soap is made from fine white curd soap, one hundred and fifteen pounds; cocoa-nut oil soap, twenty pounds; perfumed with a mixture of attar of caraway, one and a half pounds; attars of thyme and rosemary, each eight ounces; and attars of cassia and cloves, each four ounces.

Brown Windsor Soap.—Curd soap, one hundred pounds; cocoa-nut oil, and pale yellow rosin soaps, each twenty-five pounds; color with caramel, eight ounces; and perfume with a mixture of attars of caraway, cloves, thyme, cassia, petit-grain, and lavender, each eight ounces. MORFIT'S oleic soap, of first grade, is peculiarly adapted as body for brown windsor soap, as it gives a rich lather, and is very smooth, and highly emollient. Moreover, it retains its normal moisture for a great length of time.

Savon au Miel—Honey Soap.—White curd soap, forty pounds; melted and crutched with white honey, ten pounds; storax, two pounds; and powdered benzoin, one pound.

An imitation honey soap is made by melting together pale yellow soap, one hundred pounds; soft soap, fourteen pounds; and perfuming with attar of citronella, one and a half pounds.

Frangipani Soap.—Curd soap, colored brown with caramel, seven pounds; perfumed with a mixture of attars of neroli and vitivert, each four ounces; attar of rose, two drachms; attar of santal, one and a half

ounces; and civet, two drachms. The latter is to be previously triturated with the attars.

Savon à la Rose.—Rose soap is made from a mixture of olive oil soap, sixty pounds; and curd soap, forty pounds; colored with one pound of finely bolted vermillion. The perfume consisting of attars of rose, six ounces; attars of santal and geranium, each one ounce; and tincture of musk, eight ounces; must be added to the cold soap in meal, and incorporated by kneading. The oil soap may be replaced by curd soap, but the quality of the rose soap will not then be so fine.

Savon au Bouquet.—White soap, sixty pounds, perfumed in the cold with eight ounces of an extract bouquet; or in warm paste, with a mixture of attar of bergamot, eight ounces; attars of cloves and sassafras, each half an ounce; attar of thyme, one ounce; attar of neroli, one ounce. The soap body must be previously colored brown with one pound of caramel. The soap scented with the attars is inferior to that having the extract bouquet as perfume. The perfume, and with it the title of the soap, can be varied according to the caprice of fashion.

Poncine Soap.—Curd soap, fifty pounds; cocoa nut oil soap, the same quantity, melted to paste and crutched with ten to twenty pounds of finely bolted pumice-stone powder. The perfume is a mixture of attars of thyme, cassia, caraway, and lavender, each one pound.

Spermaceti Soap.—The genuine spermaceti soap is superior to all others in emollient properties; but it is rarely made from pure stock, owing to the difficulty in saponifying it. As generally vended, it consists of white curd soap, fourteen pounds; perfumed with a mixture of attars of bergamot, two and a half pounds, and attar of lemon, eight ounces.

Palm Soap.—Curd soap, made of a mixture of one-half lard, one-third bleached palm oil, and the remainder olive oil or spermaceti, constitutes the body of palm soap. Its natural odor is that of the violet, which is sometimes stimulated by the addition of a little attar of portugal, with a lesser portion of attar of cloves.

Floating Soap.—All the hard soaps increase in bulk by mechanical batting of the paste; the loss of density thus produced gives them the property of floating in water. The batting or whipping is best accomplished by means of a churn-twirl, rotating on a pivot in the bottom of the melting-pan, and put in motion by a handle.

Transparent Soap.—This amber-looking soap is made by dissolving hard white soap, previously reduced to meal and thoroughly dried, in alcohol of 66° Twaddell. The steam-bath before described, fitted with a still head, makes a very appropriate containing vessel. The alcohol and soap are taken in about equal proportions; and as the solution proceeds, any spirit which may distil over must be allowed to condense in a worm, and collect in a receiver. The heat should not exceed 212°. After solution, the whole must be allowed repose for settling, after which the clear, supernatant fluid is to be drawn off from the sediment into wooden frames, or globular moulds of britannia metal, if it is desired to cast it in ball form. Previous to settling, it may be colored as desired—red, with tincture of alkanet; yellow, with tincture of turmeric;

orange, with a mixture of the two tinctures; green, with tincture of chlorophyle; and blue with tincture of indigo carmine. Transparent soap is rather translucent when first made, and does not clear until perfectly dry. The perfumes are the same as for the other soaps.

SOAPS BY THE COLD PROCESS.—All the foregoing soaps are made by boiling the fat stock with alkali; but toilet soap may also be made extemporaneously without much heat and the so-called little pan process. Many of the French and American perfumers manufacture their soaps in that way. The lies are necessarily very strong, and should be of 66° Twaddell. Cold soaps are very white, and also very hard, as they do not contain any excess of water.

White Soap.—Lard forty pounds, and caustic soda lie, of 64° Twaddell, twenty pounds. Melt the fat by a heat not exceeding 150°, and add, during constant stirring, ten pounds of the lie. After one hour's manipulation with the stirrer, the heat being continued all the time at a moderate degree, the remaining ten pounds of lie are to be added. When the paste has become smooth and uniform throughout, it is transferred to a cooling frame, perfumed, and left in a room of moderate temperature for a few days to set and ripen. It is then ready to be cut into tablets and pressed.

Almond Soap.—Genuine almond soap is made from oil of sweet almonds, fifty pounds; and soda lie of 66° Twaddell, twenty-five pounds, the latter being gradually added to the former at a temperature between 125° to 150°, and the whole stirred constantly until the mixture has a pasty consistence. It is then transferred to a cooling frame, perfumed with attar of bitter almonds, and then left for several days to set and ripen.

Soft Soaps.—These differ from the hard soaps in having potassa in place of soda as their alkaline base. They are all more or less pasty or gelatinous; and they may be made either by the boiling or cold process. Of the soft soaps used in perfumery, that known as *fig soap* is, however, the only one that is boiled.

Fig Soap.—The fat stock is chiefly oil—generally olive oil—with the addition of a little tallow to give it the granular appearance called *fig*.

Shaving Cream.—This saponaceous compound is made by melting twenty pounds of lard in the steam-bath, at a temperature of 212°, and then letting five pounds of caustic potassa lie, of 66° Twaddell, run in *very slowly*, during constant stirring and batting with a wooden paddle. The heat is continued all the time; and after a while, when the paste becomes thick, five pounds more of lie are added in the same manner. After several hours' stirring the paste becomes firm, and is then finished. It is then transferred to a mortar and triturated, until the soap becomes homogeneous throughout, and assumes a pearly appearance. Attar of almonds is the perfume for almond cream, and attar of rose for the rose cream, and they are dissolved in a little alcohol, and added during the trituration. The rose cream is colored at the same time with a little tincture of alkanet.

Rypophagon Soap.—This is a mixture of equal parts

of pale yellow rosin soap and fig soft soap, perfumed with attars of anise and citronella.

According to PRESSÉ, British India and Europe consume annually, at the lowest estimate, upwards of one hundred and fifty thousand gallons of perfumed spirit, under various titles, such as eau de cologne, lavender water, esprit de rose, *et cetera*. Some idea of the commercial importance of this art may be formed, when one of the large perfumers of Grasse and Paris employs yearly eighty thousand pounds of orange flowers, sixty thousand of cassie, fifty-four thousand of rose leaves, thirty-two thousand of jasmin blossoms, twenty thousand of violets, and sixteen thousand pounds of lilac, besides rosemary, mint, lemon, citron, thyme, and other plants in larger proportion.

The Editor cannot conclude this monograph without expressing his thanks to Dr. CAMPBELL MORFIT of New York for the valuable assistance he has rendered him during its compilation. Professor MORFIT is the author of one of the best books on this subject which has recently appeared; and being the first technological chemist in America, the Editor, although personally unknown to him, feels the more gratified for his having volunteered his aid in this article, which is sure to prove interesting to all readers, whether scientific or otherwise; for, as shown in the introductory notice, perfumes, in the early ages of the world, were in constant use, and had the high sanction of Scriptural authority.

PHOSPHORUS.—*Phosphore*, French; *phosphor*, German; *phosphorus*, Latin.—This truly remarkable substance is one of the elementary bodies. It occurs abundantly in both kingdoms of nature, not, however, in the free state, but always in combination, usually as phosphoric acid united to earthy and metallic bases. Its intense affinity for oxygen would not allow it to exist in nature in an isolated form; for on exposure to the air, even at the ordinary temperature, it undergoes a slow combustion, and is converted into phosphorous and phosphoric acid. At a very slightly elevated heat it takes fire, and is resolved entirely into phosphoric acid. Nor is phosphoric acid met with naturally uncombined, its powerful reaction upon the bases causing it to enter quickly into combination. Amongst phosphorus compounds, the most important are those which phosphoric acid forms with lime and magnesia, and these are widely distributed throughout nature. In this condition it is found in unstratified rocks, and in the lavas of more recent date. As these disintegrate, and crumble down into fertile soil, the phosphates pass into the organism of plants, and ultimately into the bodies of the animals to which these latter serve as nutriment. Phosphate of lime constitutes by far the greatest part of the hard matter of bones, and consequently fulfils a very important part in the structure of the animal frame, communicating stiffness and inflexibility to the bony skeleton. Phosphorus is also an ingredient, in some unknown form of combination, of animal and vegetal fibrin and albumen. It is likewise found in the brain, and in the soft roe of the carp, though in what particular condition it exists is uncertain. In the urine and excrements it is also invariably present. In the mineral kingdom, it

is found principally as phosphate of lime—known to mineralogists as apatite—as phosphate of magnesia, as phosphate of alumina, or wavelite, and as phosphates of lead and copper, *et cetera*.

The term phosphorus—derived from two Greek words signifying *light-producer*—was applied by the older chemists to every species of substance capable of becoming luminous without the application of heat. It is now retained only by the one simple substance under consideration.

HISTORICAL NOTICE.—Amongst the many important discoveries made by the alchemists in their pursuit of the philosopher's stone, that of phosphorus holds a very high position. It was first obtained, in 1667, by BRANDT, a tradesman of Hamburg, while engaged in prosecuting researches upon urine, with the view of extracting from it the mysterious agent that would effect the transmutation of the baser metals into gold. BRANDT partially explained the secret to KUNCKEL, a German chemist with whom he was acquainted, and who subsequently succeeded in obtaining it even more pure than had been done by BRANDT. He continued to prepare it, and it soon became known as KUNCKEL'S phosphorus, to distinguish it from other bodies possessing the property of luminosity. In 1676 KUNCKEL published a description of it, and was afterwards considered as one of its discoverers.

In England, the celebrated BOYLE, having seen phosphorus in the hands of KRAFT of Dresden, who had purchased the secret from BRANDT, and knowing that it was extracted from some matter appertaining to the human body, commenced his investigations, which, after a year's labor, were crowned with success. In 1680 an account of the new substance was published in the Philosophical Transactions, and it became known under the name of English phosphorus. BOYLE communicated his process to GODFREY HANKWITZ, who prepared it under his direction in London, in large quantities; and after the death of BOYLE and KUNCKEL, HANKWITZ was alone in possession of the secret and the trade in this substance. Up to this time it was extremely rare, being found only amongst the cabinet curiosities of the rich; and for the next fifty or sixty years its great price prevented its employment in any branch of art or manufacture. At last, in 1737, a stranger came to Paris, and sold to the French government a process for its preparation, which HELLOT, conjointly with GEOFFROI, DUFAY, and DUHAMEL, was charged to submit to the test of experiment. The process was successful, and a report of it was published in the Memoirs of the Academy for the year 1737. By this method, also, it was extracted from urine, and although the process succeeded it could never have been employed on the large scale. It was besides tedious and offensive. To understand the difficulties it will be sufficient to say, that, after a protracted series of operations, the above-mentioned chemists obtained from five hogsheads of urine, thirty-eight pounds of the residue on evaporation, the whole of which yielded only four ounces of phosphorus, and by means of four distillations.

Experiments were afterwards made by MARGRAAF, FOURCROY, VAUQUELIN, and others, to render the

process of extracting it from urine more easy, but this process was entirely relinquished when SCHEELLE and GAHN discovered the presence of phosphoric acid in the bones of animals. It is from bones that phosphorus is still extracted at the present day. It is prepared as an article of manufacture in large quantity in London and Paris. KANE has calculated that in the latter city alone, about two hundred thousand pounds are yearly produced. In Germany, also, it is manufactured on a large scale; one establishment at Carlsruhe—that of OTTO PAULI—producing annually, amongst a long list of other chemical substances, sixty hundred-weight of this one article. Its ready inflammability has always made it a subject of popular interest, while the singularity, importance, and variety of its compounds, have drawn to them no ordinary share of the attention of chemists. The introduction of lucifer matches has enormously increased its consumption; indeed, at least ninety-five per cent. of the whole quantity produced is absorbed by this manufacture.

PREPARATION.—All the processes for obtaining phosphorus are founded upon the deoxidation of phosphoric acid— PO_5 —by means of carbon.

BRANDT and BOYLE evaporated urine to a thick creamy consistence. This was afterwards distilled, either *per se*, or after being mixed with sand or charcoal powder. In this process the carbon—either that which results from the charring of the organic matter contained in urine, or that which is added to it—decomposes the portion of the phosphoric acid which is in combination with ammonia, while that which is combined with the soda remains unaltered. MARGRAAF evaporated urine to the consistence of honey, then added one-tenth of chloride of lead, and half its weight of charcoal powder. The mass was afterwards thoroughly desiccated, and then distilled. In this case the chloride of lead and phosphate of soda mutually decompose, yielding phosphate of lead and chloride of sodium :—

GIOBERT precipitated urine, without previous evaporation, with a soluble salt of lead. The precipitate of phosphate, sulphate, and chloride of lead was collected, well washed, and mixed with a fourth of its weight of powdered charcoal. The mixture was then exsiccated and distilled. The great advantage in the processes of MARGRAAF and GIOBERT was, that an equal quantity of urine yielded nearly twice as much phosphorus as the process of BOYLE and BRANDT, in consequence of the decomposition of the phosphoric acid originally in combination with soda, and which in the process of the latter chemists would remain unaffected.

After the discovery of phosphoric acid in the bones of the vertebrata, the old methods of extracting phosphorus from urine were totally abandoned, and it is now obtained almost exclusively from bones. Phosphoric acid exists in bones in the annexed form :—

the bones are first thoroughly calcined, that is, heated to redness, with contact of the air, until the organic matter is entirely removed. The bone ash thus obtained is reduced to powder, and to every three parts are added two of concentrated sulphuric acid, and sixteen or eighteen parts of water. By this treatment a portion of the lime is separated as sulphate, and an acid phosphate of lime is produced, which dissolves in the supernatant liquid. After the separation of the sulphate by decantation and filtration, the phosphoric solution is concentrated by evaporation to a thick sirupy consistence. A quantity of charcoal powder, equal to one-fourth of its weight, is then added, and the pasty mass is exposed to a strong heat, nearly to redness, till perfectly dry. The desiccated mass is then transferred to a stone-ware or iron retort, connected by a wide elbow-shaped copper tube with a receiver containing water, into which the tube dips about a line. Another smaller tube, open at both ends, is attached to the receiver, to convey the uncondensed gases into the chimney. Heat is now applied, and is gradually increased to whiteness. The superphosphate of lime, in contact with charcoal, is decomposed, the lime retaining only the quantity of phosphoric acid necessary to reconstitute bone earth. The excess of acid, and the water still remaining in the mass, are deoxidised by the charcoal, and the results are carbonic oxide, hydrogen, and phosphorus. The phosphorus gradually rises in vapor, distils over, and is condensed in yellow drops in the water contained in the receiver, at the same time that the gases escape by the smaller tube into the chimney.

The theory of this operation is very simple, but in practice many difficulties occur, and the requisite precautions will be pointed out in the following detailed account of the process.

Preparation of the Bone Ash.—The bones usually employed in this manufacture are those of oxen, of sheep, or of horses. The bones of sheep are preferred, as the ash which they yield is less compact, and more easily attacked by an acid. They contain, besides subphosphate of lime, carbonate of lime, and a small per centage of other salts, as phosphate of magnesia, chloride of sodium, fluoride of calcium, *et cetera*; also a large proportion of animal matter, estimated at from thirty-three to fifty per cent., according to the kind of bone, and the age of the animal. The following analysis of the bones of the ox is by BERZELIUS :—

	Centesimally.
Animal matter soluble by boiling, and vascular substance,.....	33·30
Phosphate of lime, with a little fluoride of calcium,.....	57·35
Carbonate of lime,.....	3·85
Phosphate of magnesia,.....	2·05
Soda, and a little chloride of sodium,.....	3·45
	100·00

The object of the first operation is to cause a complete separation of the animal matter. This is usually effected by calcination. The process is conducted in a large reverberatory furnace as follows :—The fire is first well kindled; a quantity of bones are then introduced by the opening in the dome of the furnace. When these are well inflamed, a further supply is added until the furnace is about half filled. A strong

draught is created by placing on the cupola, surrounded by a cone, a stove pipe, more or less elevated, and which is directed into the chimney. The operation now goes on of itself, and the combustion is very complete. When concluded, the ash is drawn out at the furnace door, and a fresh charge introduced at the upper opening, being careful not to add a too great quantity at one time, and also to maintain the necessary draught, so that the operation may not be suspended. The calcination is effected at little expense, as the bones themselves yield the necessary combustible matter. When first heated, they become black, owing to the disengagement of hydrogen, oxygen, and nitrogen gases, and the consequent separation of charcoal. A considerable time is required to remove the whole of the charcoal from the osseous mass; and if, when the ash is drawn out, many black portions remain, they are returned to the kiln, and recalcined.

Very frequently bones are used in this manufacture from which the soluble gelatinous matter has been previously extracted. When these residues are collected in heaps, a rapid fermentation ensues, and they become heated and perfectly dried. They are afterwards burned in a reverberatory furnace, or one of similar construction. Before introducing the bones, the bed of the furnace is heated to redness. They are submitted to the action of the flame for the space of twenty hours, at the end of which time the incineration is usually complete.

The incombustible residue of these operations consists of about eighty to eighty-two per cent. of a phosphate of lime— $6 \text{ Ca O} + 3 \text{ PO}_5$ —fifteen to seventeen of carbonate of lime, and two or three of sand, earthy matter, chloride of sodium, *et cetera*. According to GRAHAM, bone earth contains two distinct phosphates of lime, both tribasic, but in one of which an atom of lime is replaced by one of water. He gives as its formula— $2 (3 \text{ Ca O}, \text{PO}_5 + \text{HO}) + (\text{HO}, 2 \text{ Ca O}, \text{PO}_5 + \text{HO})$. The calcined bones are ground to fine powder and sifted. The powder is greyish-white, and almost tasteless.

Second Operation.—The object of the next process in this manufacture is to transform the insoluble calcareous phosphate into the soluble superphosphate. This conversion is effected by means of sulphuric acid, which separates a portion of the base in the form of the nearly insoluble sulphate of lime. The sulphuric acid also decomposes entirely the carbonate of lime present, producing the same difficultly soluble salt. The operation is effected in a leaden cistern or in a wooden tub lined with lead. To three parts by weight of the bone ash are added two of concentrated sulphuric acid, and from fifteen to twenty parts of water, constantly stirring with a wooden spatula. A lively effervescence ensues, owing to the escape of carbonic acid. When this has subsided, the whole is transferred to a copper boiler, heated to the point of ebullition, and to promote decomposition, continued at this temperature for twenty-four hours. The liquid requires to be constantly agitated, to prevent the concretion of the mass, which, if allowed, would protect a portion of the subphosphate from the action of the acid. When completely decomposed, the mixture is suffered to remain at rest

for ten hours, so that the sulphate of lime may subside. The supernatant liquid is afterwards drawn off by means of a leaden siphon, and conducted through leaden pipes to the filter, consisting of a conical linen bag of close texture, which retains the sulphate of lime, and allows the solution of acid phosphate to pass through. The residue itself is then thrown upon the filter and strongly pressed, and afterwards thoroughly washed with successive portions of boiling water. The filtrate is now concentrated, by evaporation in a copper boiler, to one-fourth of the original quantity, and again filtered to remove the portion of sulphate of lime which has become insoluble; the evaporation is then resumed till the liquid has a sirupy consistence. The sirup, which contains the acid phosphate of lime, the excess of sulphuric acid, and a little sulphate of lime, is gradually mixed with a quantity of powdered charcoal, about one fourth of the original weight of the bones. The mass, after being evaporated to dryness, is further dried in a cast-iron kettle, at a nearly red heat, and with constant stirring with an iron spatula. During this process, the greatest part of the water is disengaged; a portion of the excess of sulphuric acid is also set free; the remainder, by the action of the charcoal, is decomposed, and sulphurous and carbonic acids are liberated.

Distillation.—The perfectly dry mixture of acid phosphate of lime and charcoal is ground to fine powder in an iron mortar, and transferred as quickly as possible into the retorts. These, which are of earthenware, are arranged side by side in a reverberatory furnace, as shown in Fig. 396. The neck of the retort fits into the

Fig. 396.

tubulure of a copper receiver half filled with water, and furnished with a tube for the escape of the gas formed during the distillation. Each retort has its own receiver, and all the receivers are placed in a trough filled with water, at the temperature of about 110° , and kept at that temperature, in order that the phosphorus distilling over may not solidify and obstruct the tubulure. In performing the distillation, a very high temperature is required. The furnace should therefore be sufficiently capacious to hold a body of coke or charcoal piled above the retort. Earthenware retorts at a red heat become permeable to the vapor of phosphorus, and consequently require to be well and carefully luted externally. For this purpose a mortar, composed of clay and horse dung, may be applied, or, still better, a mixture of freshly slaked lime and solution of borax. This mixture should be laid on with a brush in two or three successive coats, and forms, according to BRANDE, an excellent vitrifiable lute. The copper tube opening into the receiver, and into which the beak of the retort is inserted, should be of considerable size, and so bent as to dip perpendicularly into the water, otherwise it will be apt to become plugged up by congealed

phosphorus. It must also dip so little, that by no condensation could the water be forced back into the retort. The heat of the furnace in which the retorts are placed should be very slowly raised, allowing at least three hours to heat to redness; afterwards it is urged vigorously till all disengagement has ceased, the process requiring from fifteen to thirty hours, according to the size of the retorts. The superphosphate of lime, although dried at a high temperature, retains chemically-combined water, which is liberated by the superior heat of the furnace. At first, therefore, a mixture of air and steam is disengaged; afterwards, when the charcoal becomes incandescent, a mixture of hydrogen and carbonic oxide, evidently proceeding from the decomposition of the water by the hot charcoal— $\text{HO} + \text{C} = \text{H} + \text{CO}$. When the retort has attained a bright red heat—that is, after the lapse of about four or five hours—the nature of the gaseous products is changed. The superphosphate of lime is decomposed into basic or subphosphate of lime, and phosphoric acid. This last, in contact with incandescent carbon, yields phosphorus, which rises in vapor, distills over, and condensing in the liquid form in the tubulure, flows down and collects under the surface of the water. The phosphorus is accompanied by a mixture of carbonic oxide and phosphide of hydrogen, the last inflaming spontaneously on contact with the air. These two gases continue to be produced during the whole operation. DUMAS considers it an unsettled question, whether the gas evolved is really phosphide of hydrogen, and if it is not carbonic oxide saturated with the vapor of phosphorus, as a small quantity always escapes condensation, and this is sufficient to render carbonic oxide spontaneously inflammable by contact with the air. The disengagement of gas enables one to trace the progress of the operation, and when it has entirely ceased, the process is terminated. In the retorts are found a subphosphate of lime—having precisely the same composition as the original bone phosphate, $6\text{CaO} + 3\text{PO}_5$ —and also the redundant charcoal. The lime of the phosphate acts a most important part in fixing the phosphoric acid, which, if not so combined, would distil over long before the heat was sufficiently high for decomposition.

The proportion of the various ingredients used in the production of phosphorus, is varied by different manufacturers. FUNCKE used, for one hundred parts of bone ash, ninety parts of concentrated sulphuric acid, and nine hundred and fifty of water. This mixture is digested for a considerable time in a leaden vessel, then transferred to a linen filter. The filtrate is afterwards evaporated to the consistence of sirup, mixed with twenty parts of charcoal powder, and dried. By distillation this mixture yields ten parts of phosphorus. NICOLAS used equal weights of bone ash and oil of vitriol. Various other methods have also been proposed for procuring phosphorus from bone ash. SCHEELÉ dissolved the ash in nitric acid, and precipitated the lime by sulphuric acid. The rest of the process is conducted as above. FOURCROY and VAUQUELIN prepared acid phosphate of lime according to NICOLAS' method, and precipitated its aqueous solution with acetate of lead. The resulting phosphate of lead was afterwards distilled with one-sixth of its weight of

charcoal. BERZELIUS dissolved bone ash in warm nitric acid, and precipitated the hot solution with acetate of lead. Native phosphate of lead may also be employed, provided it is free from arseniate.

Purification.—The phosphorus obtained by any of the above processes is never in a state of purity, as it passes into the receivers. The ordinary impurities are adhering charcoal, a reddish-brown phosphide of carbon formed during the process, and another reddish-looking substance, originally supposed to be an oxide of phosphorus, but ascertained by SCHRÖTTER to be phosphorus in an allotropic condition. Phosphorus, otherwise pure, generally contains a small quantity of this amorphous modification of the element. Arsenic is also frequently present, in consequence of the acid used in its preparation having been formed by the combustion of arsenical sulphur, or pyrites. WITTSTOCK found in one sample of phosphorus 0.76 per cent. arsenic. The same chemist examined a sample of phosphorus obtained from France, the coating of which was greyish-yellow instead of white. It appeared, when freed from this coating, of a dark-red color by transmitted light. Its fractured surface was almost black, and it retained this color when melted and slowly solidified. Besides arsenic he found it to contain bismuth, lead, iron, copper, and a large quantity of antimony.

Most of the impurities may be separated by simple fusion in hot water, and afterwards pressing through buckskin, or still better, chamois leather. The operation is effected in the apparatus represented in Fig. 397. The phosphorus is first agglomerated by melting it in a water bath at 140° . When it has again solidified by cooling, it is wrapped in a perfectly clean

and well-moistened chamois skin, *c*, which is then tied up, and immediately plunged into a copper colander, placed in the middle of another vessel, *A*, filled with water, heated to about 120° Fahrenheit. When completely fused, the bag of skin is pressed upon by a wooden capsule, *D D*, by means of the lever, *G G*, increasing the pressure very gradually. The melted phosphorus passes through the pores of the skin, and collects in the liquid form at the bottom of the vessel.

PAYEN gives a description of a process by which the purification is rendered more complete, obviating at the same time all danger in the manipulation. It consists in causing it to pass, when in a state of fusion, through granular animal charcoal. The apparatus consists of a cylindrical vessel provided with a false bottom,

pierced with small holes, on which is laid the charcoal in a layer to the height of six or seven inches. The cylinder is then filled to two-thirds with water heated to 140° Fahrenheit, and the phosphorus, as taken from the receivers, is introduced. Being quickly melted, it passes spontaneously through the charcoal filter, and collects under the false bottom. It is afterwards strained by hydrostatic pressure through chamois skin.

Several other methods have been followed to effect the separation of the red amorphous phosphorus. It may be removed by digestion for a considerable time, and with frequent agitation, in very dilute nitric acid, or in chlorine water, contained in a cask fitted with a gas delivering tube, which dips under water.

The redistillation of phosphorus is occasionally resorted to as a means of purification. On account of its excessive inflammability, the process demands great care and attention. DUMAS recommends for the distillation of phosphorus a double U-shaped tube, into the first curve of which the phosphorus to be distilled is placed, the other curve serving in place of a receiver. The arrangement is afterwards connected with an apparatus from which issues a current of perfectly dry hydrogen, or carbonic acid gas. The phosphorus, when submitted to heat, volatilizes, and distils over with the gas, and is condensed in the second curve of the tube, from which it is removed after being melted in hot water.

MOULDING.—Phosphorus, as usually met with in commerce, is either in the form of round sticks, or granular. The moulding into sticks is effected by allowing it when fused to flow into glass tubes. A method frequently adopted is simply to plunge a slightly conical glass tube into the phosphorus melted under water, and causing it to ascend the tube by drawing out the air by suction with the mouth, being careful to have a layer of water between the phosphorus and the mouth. When the required quantity has entered the tube, the upper end of the latter is closed with the finger, and the whole is immediately transferred to a vessel filled with cold water. The removal of the phosphorus from the tube may be accomplished by gently pushing with a stout wire through the narrow end of the tube.

A very simple, and at the same time very efficient, mode of forming phosphorus into sticks, has been contrived by SCHUBERT. By the old system, the glass tubes, into which the phosphorus was poured to solidify, were frequently broken in forcing the phosphorus out by means of wires, and the method was, moreover, attended with great loss of time. In SCHUBERT'S arrangement the melted phosphorus flows from a copper receiver into horizontal glass tubes, the one extremity of each tube being surrounded by water at a temperature above 111°; the other by cold water. By suddenly opening a stopcock, and again quickly closing it, a small quantity of phosphorus is allowed to pass through the glass tubes into cold water contained in a cistern, and in passing it closes the tubes, leaving a projecting rough piece of phosphorus, which forms an excellent handle, whereby to draw the sticks from the tubes. The operation thus commenced, the cock is again opened, and the phosphorus drawn alternately from either tube, cut off with a pair of strong scissors, and allowed to

fall into the cistern. By this method, from fifteen to twenty pounds of phosphorus may be formed into sticks in less than a quarter of an hour.

To obtain phosphorus in the granular condition, it is caused to fall in drops into cold water. SCHUBERT'S apparatus will also be useful in this operation. The cistern, is filled to about three parts with cold water, and upon the surface of this is placed a layer of water, heated to about 140° Fahrenheit, high enough to cover the glass tubes which convey the phosphorus from the boiler. This is done by pouring the hot water upon a wooden trencher, swimming on the surface of the cold water. The difference in the density prevents the cold water mixing with that at a higher temperature. The stopcock of the vessel containing the melted phosphorus is slightly opened, so as to allow it to exude in drops. These, falling through the mass of cold water, become solid, and collect in the granular condition at the bottom of the cistern. Phosphorus may also be granulated by shaking it, while in the fused state, with a warm liquid, till it solidifies. CASSARCA recommends for this purpose strong alcohol.

PROPERTIES.—Phosphorus at the ordinary temperature, when perfectly pure, is a soft solid substance, transparent and colorless. As generally found in commerce, it is of a light amber yellow color, or even reddish, much resembling in appearance imperfectly bleached wax. After rapid cooling it is yellow, and semi-opaque like horn, and has a waxy lustre. At 32° it is brittle and crystalline in its fracture. At a higher temperature it is soft and very flexible, may be several times bent in contrary directions without fracture, and is easily cut with a knife. The addition of an extremely small quantity of sulphur, even a three hundredth part, is sufficient to render it brittle. Being totally insoluble in water, it is tasteless; its solutions in other liquids have, however, an acrid disagreeable taste. Neither has it any smell, though on exposure to the air it gives off vapors, which, undergoing a slow combustion, have an odor somewhat resembling that of garlic, or of impure hydrogen. Its specific gravity at 60° is 1.77, and at 212° according to SCHRÖTTER 1.83. Its atomic weight, according to BERZELIUS, is 31.36. Many chemists, however, take it in their calculations at 32.

Exposed to heat it quickly melts. Its fusion commences at 108°, and in close vessels even at 95°. When melting it undergoes a dilatation of 0.0134 of its volume, according to GRAHAM, and immediately before fusion becomes transparent and colorless. It forms a transparent, oily-looking, colorless fluid, possessing a high refracting power. When completely fused, and allowed to cool slowly and without agitation, it remains liquid at 100°, or even at a lower temperature; and during solidification, the temperature rises to 108°. It begins to evaporate at 217.5°, and boils at 550°, forming a colorless vapor, the density of which DUMAS gives at 4.353, air being unity. Phosphorus volatilizes at temperatures considerably below its boiling point, and in small quantities even at ordinary temperatures, as well *in vacuo* as in the open air. Several gases, as oxygen, hydrogen, carbonic acid, nitrogen, *et cetera*, when placed in contact with phosphorus, become charged

with its vapor, and if boiled with water, it renders the aqueous vapor luminous.

Phosphorus is quite insoluble in water, but soluble—particularly if heated—in absolute alcohol, in chloroform, in fixed and volatile oils, in native naphtha, and most of the liquid hydrocarbons, in chloride of sulphur, sulphide of phosphorus, and in ether. Its best solvent, is, however, bisulphide of carbon, which dissolves one-fourth of its weight. Phosphorus crystallizes in regular octohedrons, and in rhomboidal dodecahedrons. Small octohedral crystals have been obtained by slowly cooling large masses of phosphorus. If a mixture of two parts of phosphorus and one of sulphur be melted under water, a compound is obtained, holding an excess of phosphorus in solution, and which is deposited in regular octohedral crystals on cooling. Its solution in sulphide of carbon, or in hot naphtha, when slowly evaporated in a current of carbonic acid gas, deposits regular dodecahedral crystals of considerable size.

SCHRÖTTER has carefully examined the boiling points of phosphorus under different pressures, and obtained the following results:—

Imperial inches.	Degrees.
4.72	329
6.81	338
8.03	356
10.40	392
13.30	408
14.10	424
15.40	439
20.20	446

When phosphorus is exposed to the air, even at ordinary temperatures, it undergoes a slow combustion, appears luminous, and diffuses white vapors, possessing a peculiar penetrating alliaceous smell. The phosphorous acid, PO_3 , hereby produced, attracting moisture from the air, condenses to a liquid, and taking an additional quantity of oxygen, is converted into a mixture of phosphorous and phosphoric acids, $\text{PO}_3 + \text{PO}_5$. This slow combustion is attended with a sensible evolution of heat, which gradually reaches the point at which phosphorus takes fire. It should therefore always be preserved under water. According to J. DAVY, the luminosity of phosphorus increases with the degree of rarefaction of the air, and is equally bright even in the vacuum of the air-pump. In air compressed to four atmospheres, phosphorus does not appear luminous till the temperature is raised. Nor does it shine below 32° degrees under the usual pressure, though at a few degrees higher it is distinctly perceptible. In oxygen gas, at the ordinary pressure, phosphorus does not shine unless heated to 80° , and may even be volatilized unaltered. The dilution of the oxygen with nitrogen, hydrogen, or carbonic acid causes it instantly to burst into the luminous condition.

The absorption of oxygen during the process of the slow combustion of phosphorus, may be proved by floating a small dish or watch-glass containing phosphorus on the surface of water, and covering with a bell glass. The oxygen gradually disappears, and water rises to fill the vacuum thus created. This oxidation of phosphorus in contact with the atmosphere, renders it a very useful agent for the determi-

nation of oxygen in the analysis of air, or other gaseous mixture. For this purpose, a ball of wetted phosphorus, fused upon the end of a wire, is introduced into the mixture of gases contained in a graduated tube, and standing over mercury. It is allowed to remain in contact with it as long as white fumes of phosphorous acid are visible round the ball. The vapors of phosphorous acid are ultimately absorbed by a ball of hydrate of potassa similarly introduced. The diminution in the measure of the gas shows the quantity of oxygen originally contained in the mixture.

The luminosity of phosphorus is so excellent a test of its presence, that if a drop of an extremely dilute solution of it in bisulphide of carbon be placed on a heated plate in the dark, the presence of one twelve-thousandth part is readily detected.

Owing to its powerful affinity for oxygen, phosphorus reduces the compounds of the noble metals, when placed in contact with their solutions, and quickly becomes covered with the reduced and precipitated metal. In contact with chlorine, bromine, and iodine, phosphorus inflames spontaneously, and without the aid of heat, producing respectively, chloride, bromide, and iodide of phosphorus. When heated in a copious supply of dry air, phosphorus burns with a brilliant white light, producing white fumes of anhydrous phosphoric acid, PO_5 , which, when condensed, much resembles snow.

Owing to the changes that take place in phosphorus on exposure to the air, it is necessary, to preserve it unchanged, to inclose it either in a gas free from oxygen, or in boiled distilled water. It is best preserved in stoppered bottles, completely filled with boiled water, and to exclude light, the bottle should be inclosed in a tin case, also filled with water.

Precaution.—In consequence of the great danger incurred in the handling of phosphorus, owing to its excessive inflammability, it is necessary, in all manipulations upon this substance, that a vessel, containing a mixture of chalk or magnesia and water, be placed in such a position as to be easily accessible to the operator. Phosphorus frequently, by simple contact with the warm hand, takes fire, melts, and continuing to burn, produces a painful and most troublesome sore, inflicting indeed, in some cases, frightful injuries. The danger is in a great measure prevented by immediately immersing the hand in the above mixture, as the earthy base neutralizes the strongly caustic acids formed during the combustion, and thus prevents further penetration. Phosphorus should always, if possible, be handled only under water, as the most gentle friction causes it to ignite.

AMORPHOUS MODIFICATIONS OF PHOSPHORUS.—Phosphorus, like sulphur, under the influence of apparently very trifling causes, assumes several allotropic conditions, some of which have been already alluded to.

White Phosphorus.—This modification is gradually produced whenever phosphorus under water is exposed to sunshine or ordinary daylight. The opaque crust is yellow at first, but afterwards turns white. Its specific gravity is 1.515. It smells like ordinary phosphorus, is luminous in the dark on exposure to the air, but turns red in daylight much more quickly than colorless

phosphorus. It retains its original appearance when dried over sulphuric acid, and sustains no diminution of weight. This variety of phosphorus was, until lately, considered to be a compound of phosphorus with water, or a hydrate of phosphorus, and the formula assigned to it by PELOUZE, was $P_2 \cdot HO$. Had such a compound been proved to exist, it would have been the first exception to a well-known chemical law, that element combines only with element, and compound with compound. MARCHAND proved that the supposed compound was not a hydrate; for after having dried it over concentrated sulphuric acid, he found that it retained only 0.4 to 0.7 per cent. of water; thus showing that the water, instead of being in chemical combination, was present only hygroscopically, or in mere mechanical mixture. MULDER observing that it became red in aerated water—doubtless owing to the action of light—considered it to be a compound of phosphoric oxide and phosphide of hydrogen, and to be produced by the decomposition of water. ROSE proved it to be pure phosphorus, differing from the ordinary variety only in its state of aggregation. GMELIN, because it is not produced under water in the dark, accounts for its production on the supposition that phosphorus, under the influence of light, decomposes water, producing phosphoric oxide and phosphide of hydrogen, and that, in the dark, these two compounds are again resolved into water and finely divided phosphorus. The latter theory is probably the correct one, as it is a well-ascertained fact, that phosphorus under water, by the influence of light, does actually decompose water, and that the results of the decomposition are the two above-mentioned compounds— $7P + 3HO = PH_3 + 3P_2O$.

Liquid Phosphorus.—Phosphorus, under certain conditions, after having been fused, retains the liquid form for some time after cooling, and, according to some chemists, even continues permanently in this condition. This variety of phosphorus has the appearance of a transparent oily liquid. It may be obtained by fusing ordinary phosphorus with an aqueous solution of hydrate of potassa. Under the solution it remains liquid for several weeks at ordinary temperatures, solidifies on being agitated, or by reducing the temperature to about 27° , and afterwards fuses at its ordinary melting point. Contact with a solid body, especially with solid phosphorus, also causes it to solidify. If poured upon bibulous paper, it becomes solid as soon as the adhering liquid has been absorbed by the paper, and with particular rapidity when touched with an iron wire. GROTHUS, by heating phosphorus with concentrated alcoholic solution of potassa, obtained it in the form of an oil which remained liquid on cooling, and when heated with water, evolved phosphide of hydrogen without acidifying the water. He, therefore, considered it to be a compound of phosphorus and hydrogen.

Black Phosphorus.—Another allotropic variety of phosphorus, distinguished by its black color, was discovered by THÉNARD. To produce it, phosphorus is melted at 150° , and while in a state of fusion, is poured quickly into very cold water. OSANN states that it may be obtained also by passing ozonized

air over fragments of ordinary phosphorus for a considerable length of time; and also from the red oxide of phosphorus, procured by burning phosphorus fused under water with oxygen gas. The red oxide so obtained is boiled with concentrated solution of phosphoric acid. It thereby soon changes its color and bulk, and assumes a blackish-grey appearance. The boiling being continued, a black powder separates, whilst the mass becomes greyish-brown. OSANN, however, considered the peculiar color of this phosphorus to be owing to the presence of copper. The black variety of phosphorus is produced whenever fused phosphorus is suddenly cooled. The black color disappears, and it is reconverted into the ordinary condition by remelting, and slowly cooling.

RED PHOSPHORUS.—By far the most important allotropic modification of phosphorus is that known in commerce as the amorphous phosphorus of SCHRÖTTER, or *red phosphorus*. It was originally supposed to be an oxide, and its formation was attributed to the presence of moisture. BERZELIUS was the first who understood and described the precise nature of this substance. It was afterwards minutely investigated by SCHRÖTTER and others, who have shown in a variety of ways that the red substance is nothing but phosphorus in a peculiar state of aggregation. The latter chemist published in 1848 a description of it, and the method of procuring it. He placed perfectly pure colorless phosphorus, dried as completely as possible, in a glass tube, having a bulb in the centre, and passed pure and dry carbonic acid gas over it. The phosphorus was then gradually heated to 212° to drive off every trace of moisture, and the tube afterwards sealed hermetically, thus excluding every trace of oxygen. The phosphorus when exposed to light assumed a *red hue*, the depth of which increased in intensity the longer it was exposed to the light. The same results were obtained in hydrogen and nitrogen gas. Hence he concluded that the peculiar change of condition could not be ascribed to oxidation. SCHRÖTTER proved also that the alteration might be effected by heat. In a retort, to the neck of which a glass bulb was attached by fusion, he placed a quantity of dry phosphorus in the bulb as well as in the body of the retort. The extremity of the neck was connected with a glass tube thirty inches long, placed vertically, with its lower end dipped under mercury. The neck of the retort above the bulb was filled with chloride of calcium, and a thermometer inserted through the tubulure. The phosphorus in the bulb was then heated till inflamed, and all the oxygen contained in the retort was thus absorbed. The body of the retort was now heated to 212° , to expel adhering moisture, and then left to cool. Afterwards the phosphorus was gradually heated. At about 300° , sublimation commenced, but without change of color. At 439° , the phosphorus, after some time, assumed a carmine color; it likewise became more tenacious, and the color increased in intensity until perfect opacity was produced. This change was owing to the separation of a red powder, which settled to the bottom of the vessel, and rapidly increased in quantity till it extended throughout the whole mass. SCHRÖTTER afterwards obtained it in the coherent form, by exposure during several days in a

closed glass tube to an uninterrupted heat. This red phosphorus is obtained whenever ordinary phosphorus is exposed to light, either under water or alcohol, or *in vacuo*, or in hydrogen, nitrogen, carbonic acid, carbide of hydrogen, or any gas in which it cannot oxidise; and also by exposure to heat between 419° and 480° . The change takes place, though slowly, at 419° ; but it is most rapid between 464° and 480° . It is accelerated also by the action of light. By heat alone, under diminished pressure, the conversion is slower, and does not appear to be produced when the pressure is reduced below $15\frac{1}{2}$ inches. In direct light, the metamorphosis is very active, but is perceptible also with a faint diffused light.

The following process for preparing this variety of phosphorus is extracted from MILLER'S comprehensive work. It is effected in the apparatus shown in Fig. 398. A quantity of dried common phosphorus is placed in the flask, A, to the neck of which a long narrow tube, *b*, bent downwards, is attached, the open end of which dips into a little mercury. The

Fig. 398.

removal of the air from the flask is accomplished by means of a current of carbonic acid evolved from the bottle, E, containing marble and hydrochloric acid; the gas is dried by passing it over chloride of calcium, contained in the tube, F. The flask being emptied of air, the tube is closed by fusion at the narrow portion, *a*, and the apparatus evolving carbonic acid is detached. The flask is then heated by means of an oil bath, *c*; the phosphorus melts readily; and by regulating the heat steadily between 450° and 460° , by means of a thermometer, *t*, and maintaining it thirty or forty hours, nearly the whole will be converted into the solid amorphous variety. When the metamorphosis appears to be complete, the apparatus is allowed to cool. Any unaltered phosphorus is separated by digestion in bisulphide of carbon, in which amorphous phosphorus is insoluble. The latter is afterwards collected on a filter, and washed with bisulphide of carbon as long as anything is removed from it, which

may be ascertained by evaporating a small portion in a watch-glass, when any dissolved phosphorus will remain behind.

The red powder obtained by the above process, if not quite free from ordinary phosphorus, inflames spontaneously, but if quite pure suffers no alteration by exposure to the air. To effect complete purification it should be boiled in solution of potassa of specific gravity 1.30, and then washed first with water slightly acidulated with nitric acid, and lastly with pure water. The color of this amorphous phosphorus is deeper the higher the temperature at which the transformation is effected; and in that of the finest specimens is more brilliant than vermilion. By heating the phosphorus more strongly during its preparation, the change may be effected much more rapidly; but the phosphorus then assumes the form of coherent flakes, which are difficult to purify, and are not easily detached from the vessel in which they are prepared. The process, however, requires great attention, and is not unattended with danger; as if the red phosphorus is heated to near 500° , the whole mass suddenly returns to the condition of ordinary phosphorus, with a copious disengagement of heat, succeeded by the sudden formation of a large volume of the vapor of phosphorus. Red phosphorus, therefore, appears to contain a large quantity of heat in the latent condition, which is liberated as it passes back into the ordinary vitreous state.

In 1848 a patent was granted to ARTHUR ALBRIGHT of Birmingham, for an invention communicated to him by SHRÖTTER of Vienna, for improvements in the manufacture of phosphorus, and in the apparatus to be used therein; and a Great Exhibition medal was awarded to him for the introduction of the prepared phosphorus as an article of commerce. By this process, red allotropic phosphorus is prepared on a considerable scale by Messrs. STURGE, also of Birmingham. A vertical section of the apparatus employed is represented in Fig. 399, and a view of it, as seen from above, in Fig. 400. AA is a cast-iron vessel set in brick-work, and having a fireplace underneath, with suitable flues, FF. From the inside of the flange of this vessel, a similar vessel, BB, of the same material, is suspended, and secured by means of the screw-pins, HH. The space between the two vessels contains a metallic bath, composed of a mixture of equal parts of tin and lead. G is a cast-iron cover to the inner vessel, B, fitting the upper edge by means of a groove, and fastened to the outer vessel, A, by the screw-pins, HH. A screw, S, passes through a three-armed iron holder, which is attached to a third movable iron vessel, CC, placed in a sand-bath, N. In the interior of this iron vessel, CC, another vessel of glass or porcelain, DD, is fitted, in which the phosphorus to be operated upon is placed. J is a curved pipe of iron or copper, passing freely through the cover, G, but screwed into the cover, E, and having an exit at the extremity into a detached vessel, KK. This contains water or mercury; if the latter be employed, it should be covered with water. The pipe, J, immersed in the mercury or water, serves as a safety valve, preventing the return of the atmospheric air into the inner vessel,

c c. The spirit lamp, L, is placed under the pipe, J, and is used, if necessary, to heat the curve, and prevent condensation of gaseous phosphorus, which, if allowed, would obstruct the passage. The stopcock, x, is used to prevent the ingress into c c of the contents of κ κ,

Fig. 399.

or of atmospheric air, and should be closed as soon as the operation is concluded, and before the apparatus in the furnace is allowed to become cool, or the vessel, κ κ, is removed. The cover, G, is not essentially necessary, its principal use being to prevent accidents. Between the end of the screw, s, and the cover, E, a small but strong concave disc or spring of steel is inserted, and so adjusted as to give a slight play to the

cover, E, in case of violent action arising in the interior, or the stopping up of the pipe, J, by condensed phosphorus. If the operation is conducted with proper attention, neither of these accidents is likely to occur.

Fig. 400.

The phosphorus to be converted into the amorphous state is to be previously melted and cooled under water, and afterwards dried as completely as possible. The mode of effecting the conversion is then as follows:—The phosphorus is deposited in the inner vessel, D D, and the covers, E and G, replaced. A fire is then kindled under the outer vessel, A A, and the temperature raised to such a degree as shall be sufficient to drive off the air and other gases that may be generated in the interior vessel; these will escape at the exit of the pipe, J, which dips into the mercury or water contained in the vessel, κ κ. When mercury is employed, it is desirable to cover it with a layer of water, so that any phosphorus which may distil over, and pass down the pipe,

J, may be covered thereby. The temperature is now to be gradually increased, until bubbles escape at the end of the pipe, J, which inflame spontaneously as they enter the air. When the gas has escaped freely for some time, the temperature may be further raised to 500°. To regulate the temperature, a thermometer is placed in the metallic bath before described. The length of time during which it is necessary to maintain the temperature, depends so much on accompanying circumstances that it can only be ascertained by experience. The heat should never be raised more than a few degrees above 500°. As soon as the operation is concluded, the vessel is allowed to become cool. The phosphorus is then taken out, to effect which it may be necessary to break the glass or porcelain vessel containing it. Should it be desirable to increase the pressure on the vessels, c c and D D, the vessel, κ κ, holding the mercury may be deepened, that it may contain a greater quantity, and thus a pressure of an atmosphere or even more may be gained. In this case, it will be necessary to remove the steel spring at the end of the screw, s, as soon as the steam and inflammable gases which arise in the first part of the process have ceased to issue from the pipe, J.

The phosphorus is then to be levigated under water, and drained therefrom by means of a bag or filter. If the operation has been successfully conducted, only very slight traces of unaltered phosphorus remain in the mass. The levigated phosphorus, still moist, should, in order to purify it, be spread thinly for convenient working on separate shallow trays of sheet-iron or lead. These trays may be so placed alongside each other as to receive the heat of steam, or of a hot water bath, or of chloride of calcium, or of sand, or of each consecutively in this order; but whichever be employed, the temperature must be gradually raised, and the phosphorus frequently stirred, until the disappearance of all luminous vapor shall show that the whole of the adhering ordinary phosphorus has become oxidised. The operator should have water at hand, to quench any fire that may arise before the whole mass was perfectly oxidised. The phosphorus is afterwards to be washed until the water running from it is perfectly free from all traces of acid.

The process of oxidation recommended by the inventor of the above-described apparatus, for the removal of unaltered phosphorus from the amorphous modification, is very unsatisfactory. A far better method, and one more quickly and more easily executed, is the application of an appropriate solvent, as bisulphide of carbon, oil of turpentine, or some other liquid hydrocarbon, by which the whole of the adhering unconverted phosphorus is readily and completely removed. This means of purification is also advantageous, inasmuch as the whole of the unaltered phosphorus obtained in solution may be recovered by simple distillation of the solvent, while in the process of oxidation the phosphorus, being converted into phosphorous and phosphoric acids, is lost, the acids being dissolved and removed by the subsequent washing.

Properties of Red Phosphorus.—Red amorphous phosphorus, in the state of powder, is lustreless, and destitute of crystalline structure. Its color varies from a scarlet to

a carmine red; sometimes also to a blackish-brown tint. When in the form of coherent masses, it is reddish-brown, exhibiting perfect metallic lustre and an iron-black fracture; sometimes the lumps are also of a bright scarlet color—usually, however, dark reddish-brown. It is brittle, very fragile, with a perfect conchoidal fracture. Its hardness is intermediate between calcareous spar and fluor spar; specific gravity at 60° is 2.14, exceeding that of ordinary phosphorus. Occasionally it has a porous appearance, resembling pumice-stone in structure, while some lumps are light enough to swim upon the surface of water. When heated in a liquid, it becomes darker in color, and after some time it acquires a deep violet. It is far less combustible than ordinary phosphorus, and is not luminous in the dark. When quite pure, it will bear a tolerably high temperature; but if it contains any unaltered phosphorus, is readily ignited by slight friction or percussion. It is not altered by exposure to the air at the ordinary temperature, but at 490° it takes fire, and if heated to from 490° to 500° in an inert gas, it passes into the state of ordinary phosphorus. Red phosphorus is insoluble in bisulphide of carbon, alcohol, ether, naphtha, chloride of phosphorus, and other solvents of ordinary phosphorus. In spirit of turpentine and other liquids which boil at a high temperature, it dissolves very sparingly during ebullition, but is deposited on cooling as ordinary phosphorus. It does not unite with sulphur until heated to 444°. It combines with chlorine with evolution of heat, but without any disengagement of light. The combination with bromine is attended with light. Concentrated sulphuric acid dissolves it when heated, with evolution of sulphurous acid, but is without action upon it in the cold. It is readily soluble in nitric acid with evolution of hypophosphoric acid, and formation of phosphoric acid. A boiling solution of potassa dissolves it, with disengagement of phosphide of hydrogen, not spontaneously inflammable, and it is at the same time converted into the black modification; indeed, according to SCHRÖTER, phosphorus always passes through the red state before conversion into the black modification. Red phosphorus decomposes many metallic oxides—for example, oxides of manganese, lead, silver, copper, mercury, especially if heated, sometimes with explosion. It detonates also when gently triturated with chlorate of potassa. If not perfectly freed from ordinary phosphorus, it ignites spontaneously when fractured, and also exhibits phosphorescence in the dark, and other properties of ordinary phosphorus. According to WÖHLER, red amorphous phosphorus may be rendered colorless and perfectly transparent, by fusing it in a concentrated solution of bichromate of potassa mixed with sulphuric acid. After this treatment it usually remains liquid after cooling, but solidifies instantly when touched by a solid body.

From a comparison of the properties of red allotropic phosphorus and the ordinary variety, it will be seen that the invention of SCHRÖTER is a great boon to those engaged in manufactories where phosphorus is largely used, and particularly to producers of instantaneous lights or lucifer matches, inasmuch as the red phosphorus is perfectly free from those pernicious

qualities which render the application of ordinary phosphorus to these purposes so destructive to health. In a commercial point of view it is also advantageous, as the red variety may be transported with perfect safety, while the carriage of ordinary phosphorus is attended with considerable trouble and risk, and consequent expense.

ESTIMATION.—Phosphorus is quantitatively determined as pyrophosphate of magnesia— 2 Mg O, PO_5 —or as basic phosphate of sesquioxide of iron, being first converted into phosphoric acid by the action of boiling diluted nitric acid.

To estimate as pyrophosphate of magnesia, a weighed portion is taken, and treated with nitric acid until entirely dissolved. The solution is mixed with a considerable excess of ammonia; chloride of ammonium is then added; and lastly, sulphate of magnesia, as long as a precipitate continues to be formed. The mixture is allowed to stand twelve hours; the deposit of phosphate of magnesia and ammonia is then collected by filtration, and well washed with dilute solution of ammonia, dried, and heated to intense redness, to expel all traces of ammonia. Every one hundred parts of pyrophosphate are equal to 28.15 of phosphorus.

To determine as phosphate of sesquioxide of iron, a weighed portion of the phosphorus is taken, and oxidised as above by dilute nitric acid. To the solution of phosphoric acid thus obtained, is added a measured quantity of sesquichloride of iron, and the whole is precipitated by ammonia. The mixture is allowed to stand some time at a gentle heat, the precipitate afterwards separated by filtration, washed and exsiccated at a gentle heat, which is afterwards gradually increased to intense ignition. This precipitate is a basic phosphate of sesquioxide of iron. From its weight is deducted the quantity of sesquioxide corresponding to that of the sesquichloride of iron added, and the remainder expresses the quantity of phosphoric acid contained in the solution.

IMPURITIES.—Phosphorus is rarely adulterated, and the only impurities contained in it are those derived from the acid used in its preparation. DUMAS considers flexibility as a characteristic of good phosphorus. Occasionally arsenic, antimony, bismuth, and some other metals have been found in it. If the acid used contained arsenious acid, or an oxide of antimony, these are reduced in the process of manufacture of phosphorus, and are found in it in the metallic state. A solution of phosphorus in dilute nitric acid should give no precipitate with sulphide of hydrogen, and the precipitate procured by a barytic salt should be entirely soluble in excess of nitric acid, proving the absence of sulphur. If arsenic is present, the solution in nitric acid deposits a black precipitate of metallic arsenic when submitted to evaporation.

PHYSIOLOGICAL EFFECTS.—Phosphorus introduced into the stomach of animals acts as a caustic poison. According to ORFILA, the corrosion depends on the formation of phosphorous acid, by the oxidation of phosphorus in the pulmonary canal, and the action of this acid upon the tissue with which it comes in contact. It is very rarely used in medicine, though it has been strongly recommended in cases attended with

great prostration of the vital powers, and also in some chronic diseases of the nervous system. In small doses its operation is stimulant. It becomes absorbed, and communicates an alliaceous smell to the breath. After absorption, it excites the nervous, vascular, and secreting organs, raises the temperature of the skin, and increases the frequency of the pulse. Its general effect is that of a powerful sudorific and diuretic. In large doses it operates as an irritant poison, producing inflammation of the stomach and bowels, terminating in convulsions, insensibility, and death. It is usually administered in solution in ether, chloroform, and in oils. The antidotes to be resorted to in cases of poisoning are chalk or magnesia diffused in milk, together with mild demulcent liquids in large quantity.

STATISTICS.—Previous to the year 1845, the whole of the phosphorus consumed in this country was imported principally from the Continent of Europe. The amount of duty paid in 1844 showed a consumption of about one hundred and twenty-five hundred weight. Since that time it has been manufactured to a considerable extent in England. In 1853 the conjoined English and French product of phosphorus was estimated at one hundred and thirty-four tons. Manufactories of phosphorus are now to be found in Prussia, Baden, Bavaria, Austria, and Sardinia. At the Great Exhibition of 1851, samples were exhibited by COIGNIB and SON of Lyons, OTTO PAULI of Carlsruhe, and by SELOPSIS of Turin and Brozzo, for which the former two received prize medals. The quantity fabricated in Europe probably exceeds three hundred tons annually. PAYEN estimated the annual consumption in the manufacture of lucifer matches in France at thirty tons. In England, the consumption in this branch of manufacture is far greater, one house, that of Messrs. DIXON, near Manchester, producing from six to nine millions of the finished article daily; this enormous number requiring about five pounds of phosphorus. In Austria and other parts of Germany, on account of the abundance and cheapness of timber and labor, this branch of industry is conducted on a still more extended scale, several manufactories making daily above six millions of matches.

PHOTOGRAPHY.—Of the various applications of chemistry to the arts, there is perhaps none more interesting than PHOTOGRAPHY—the art by which the images formed in the camera obscura are fixed upon various tablets, such as glass, paper, metallic plates, leather, *et cetera*; for when it is considered that by means of suitable lenses an image may be formed of any object, celestial or terrestrial, from which light proceeds, the applications of photography appear to be unlimited, and the art assumes an intellectual character, which raises it above those other arts of civilization that merely minister in some particular way to comfort or luxury.

The word photography is derived from two Greek words signifying to *delineate by light*. It has been objected to this term, that the *luminous* rays are not those which effect the chemical changes that result in the production of an impression upon the sensitive tablet on which the image is received, but rather the violet rays of the spectrum; so that the word photography is a

misnomer. It was, however, hastily introduced, and having now become current in most modern languages, it is too late to alter it.

In point of fact, it is neither to the light nor to the heat of the solar rays that one is indebted for the beautiful results of photography, but to another mysterious power, a principle existing in combination with the light and heat of the sun, to which has been applied the appropriate name of *actinism*—a term derived from the Greek word for a *sunbeam*, and signifying merely the influence of the sun's rays, or *ray-power*, without involving the assumption of any theory on the subject.

To illustrate the composition and colored refraction of the sun's rays: suppose a beam of solar light is admitted into a darkened room through an aperture, H, in a window shutter, Fig. 401, and that it is made to pass through a prism of glass, A B C, with one of its angles downward, instead of being refracted altogether,

Fig. 401.

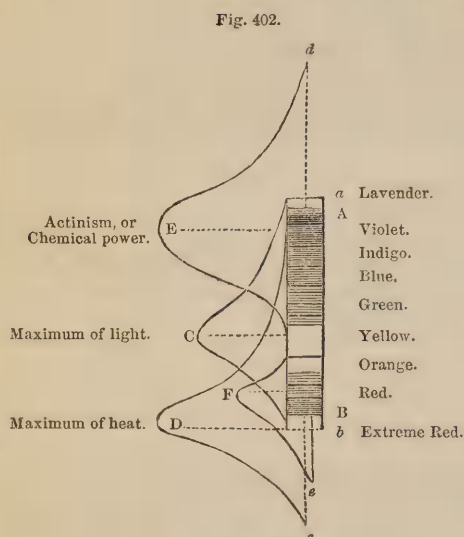

and appearing still as white light, which it does when the refracting surfaces are parallel—it is divided into several rays, and illuminates with different colors an oblong space of a white card, K L, placed to retain it. If one examines this oblong image with attention, it will be observed that it is distinguishable into seven colored bands, in the following order—violet, indigo, blue, green, yellow, orange, red. These are the seven *prismatic colors*; and the oblong image which they form is known, in scientific language, as the *solar* or *prismatic spectrum*.

The order of succession is invariable, and depends upon the unequal refrangibility of the different colored rays of which the composed white ray is made up. Thus the red ray deviates least from the direct path, S P; and the violet ray, most; and the intermediate rays have intermediate degrees of refrangibility—the orange is thrown further from the direct path than the red, and the indigo deviates less than the violet; and hence one speaks of the violet end as the most refrangible, and the red as the least refrangible end of the spectrum.

It is important to remark, however, that below the ordinary visible red, or least refrangible ray, another ray of a deeper red, distinguished as the *extreme red*, or *crimson ray*, may be detected by examining the prismatic spectrum through a deep blue glass; and by throwing the spectrum upon a piece of yellow paper, another ray appears at the violet extremity, named, by Sir JOHN HERSCHEL, the *lavender ray*.

The spectrum exhibits, therefore, when fully analyzed,

a wonderful variety of properties, of which the diagram, Fig. 402, will give a sufficient idea. In this diagram, the shaded portion represents the colors as they occur in the decomposed solar beam; the space included between A and B exhibits the Newtonian spectrum, and *a* and *b* are the rays which Sir JOHN HERSCHEL has added, thus increasing the number of the different perceptible colors from seven to nine; but all of which, as Sir DAVID BREWSTER has shown, are really reducible to three primary colors—red, yellow, and blue. The curved lines in the engraving represent the relative amount of *actinism*, *light*, and *heat*, in different parts of the spectrum. It will be observed that the actinism is

greatest at E, and ceases at *d* and *e* towards either extremity. At the point of greatest light, C, which is in the yellow ray, there is absolutely no actinic or photographic influence. At F, however, near the point of greatest heat, D, the actinic or chemical influence is sensibly felt; but this is ascribed by M. CLAUDET to the yellow rays being not merely passive or inert as regards actinic power, but having a positive destructive influence on any effects produced by the actinic rays.

Whatever be in this, it has been positively ascertained by experiment, that the *yellow*, which is the most luminous ray, has only a small heating power, while the greatest actinic or photographic power exists at that point of the spectrum where the light and heat are least sensible, and even, like the heat at the other extremity, extends a considerable distance beyond the spectrum entirely, producing effects on photographic paper where the rays of the sun are absolutely not visible.

This analysis of the refracted rays of a pencil of white light explains why a much longer exposure is required to insure a photographic image at the equator, than in Northern or Southern latitudes; the yellow rays being more abundant in the former region than in the latter, and actinism being wanting in proportion; in the latter it is *vice versa*.

HISTORICAL NOTICE.—The dawn of photography is intimately connected with researches on light. For a long time the question, whether light possessed any chemical properties, was discussed by a numerous body of scientific men. SCHEELE was the first to draw attention to the subject of the rays of the sun possessing properties able to effect chemical changes, more especially upon silver salts, and showed the comparative power of the different rays to darken them. In this department he was followed by SENEBIER, Count RUMFORD, and RITTER, who was the first to notice that solar beams, not possessing luminosity, but having a remarkable effect in inducing chemical metamorphoses, existed in sunlight. Between 1801, the period of RITTER'S researches, little was done bearing upon the origin of photography, till THOMAS, the youngest son of JOSIAH WEDGEWOOD, in 1802, published his method of producing sun pictures, by coating white paper or enamelled leather with a solution of nitrate of silver, and exposing the coated surface to the light of the sun under a painting on glass. Although he anticipated the advantages which would accrue from the art, he could not partake of them to the extent he deserved, owing to the means of fixing the impression being then unknown to him, notwithstanding the fact of Sir HUMPHREY DAVY being engaged with him in the inquiry. It appears that NIEPCE was the first who partially succeeded in fixing the image produced in the camera obscura; but this was not till 1827, long after the disclosures of WEDGEWOOD, and after many years' investigation. Previous to this period, DAGUERRE was likewise occupied with the subject, but was unsuccessful. In 1829 he entered into an agreement with NIEPCE to pursue their several researches on this subject for mutual advantage. At the period of the compact the latter published his method, which he called *heliography*. It consisted in coating a highly polished tablet of plated silver with a mixture of petroleum and essential oil of lavender, reduced to the consistency of thin varnish. After drying at a gentle heat, the prepared plate was exposed in the camera to the image thrown upon it, and after due time the latent impression was rendered visible by disengaging the unaffected parts. This was executed with a solvent composed of one part of oil of lavender, and ten of ordinary white petroleum or spirit of tar. On pouring this liquid over the plate, the impression began gradually to show itself; when sufficiently defined the plate was removed, the dissolving liquid allowed to drain off, and the operation terminated by careful washing. At this period they were anxiously seeking for a substitute for the varnish, and had recourse to alkaline sulphides and iodine for blackening the plates to form a ground for the picture; but the results were not as satisfactory even as the varnish coating, although the latter proved subsequently to be the most eligible in the hands of DAGUERRE. The heliographic method of NIEPCE was a very slow and uncertain process, requiring several hours' exposure in a strong light before a tolerably defined impression was made. DAGUERRE improved the process by using the resin of the essential oil of lavender dissolved in alcohol for the basis, and the vapor of petroleum, which

had not the effect of removing most of the varnish to the injury of the picture, as was the case in the other. From this period till that of NIEPCE's death the subject was actively prosecuted on both sides; but it would appear that the latter *savant* had lost faith in the efficacy of coating the plates with a metallic film, such as sulphide or iodide of silver; whilst DAGUERRE seemed as much impressed with these, or similar ones, being the true media for taking impressions. After the death of NIEPCE in 1833, the compact was renewed between DAGUERRE and the son, ISIDORE NIEPCE, and the research was as unflinching as before till 1839, when DAGUERRE was fortunate enough to discover the beautiful process which is now so well known under his name. It is almost needless to say, that upon the publication of the process, communicated to the Academy at Paris, the beauty of the gradations of light and shade, and the extreme delicacy and truthfulness of the pictures, took both the whole of the old and new world by surprise; and after the French Government had secured to DAGUERRE and NIEPCE a pension adequate to the importance of the discovery, and gave the process to the world, its practice became universal.

Whilst the French were diligently occupied in bringing the process of producing pictures on metallic plates to perfection, in England the subject was silently pursued by Mr. HENRY FOX TALBOT. His experiments were undertaken in 1834, with the view of rendering the image produced in the camera obscura permanent in the sun; these were prosecuted with varied success till 1839, when a paper was read by him to the Royal Society, on the thirty-first of January of that year, entitled—*Some Account of the Art of Photogenic Drawing; or, the Process by which Natural Objects may be made to delineate themselves without the aid of the Artist's Pencil*. This was the first account of this process—since called *talbotype*—methodized to the production of pictures. In February of the same year a fuller account of the preparation of the paper, and the method of fixing the picture, was communicated to the same body. TALBOT's pictures were produced on paper prepared for the purpose; and though less delicate in detail, in consequence of the inequality of the basis, than daguerreotypes, still they could be viewed with equal effect in any position, and were consequently free from the defect experienced in looking at the latter.

From this it will be evident that the British philosopher pursued his investigation independently of the French laborers in the same field; and arriving at results in a measure as satisfactory as those of DAGUERRE, he contributed, as HUNT remarks, equally with the latter most important services to *science*, in producing an instrument by which the mysterious phenomena of light could be satisfactorily investigated; and to *art*, by giving her votaries tablets upon which Nature impresses herself in all her delicacy and decision, in all her softness and grandeur, and in all her richness of tone and breadth of effect.

The fixing agent first used by TALBOT was a concentrated solution of chloride of sodium, which had the effect of dissolving the unaltered chloride of silver.

Iodide of potassium was employed for a similar purpose; but these do not give results as satisfactory as the hyposulphite of soda introduced by Sir J. HERSCHELL. Other improvements by the latter philosopher have also to be recorded, which, though not so important as the one just referred to, contribute, nevertheless, to the perfection of the art. This is particularly the case with his researches on the solar spectrum, the results of which have been already given, and by which he has laid the foundation of the principles of actinism, and brought it to its present comprehensive state.

HERSCHELL was the first to recommend the practice of saturating the saline washes used to prepare the paper with chloride of silver, and the employment of a double wash of nitrate of silver to be used in succession, alternated with drying the paper, with the view of doing away with the whitish spots so frequently seen in the pictures of TALBOT at the time; he also noticed—as likewise ROBERT HUNT—a method of fixing the impression formed in the camera with chloride of mercury, and, at the same time, rendering the paper to all appearance fit for the ordinary uses of writing and the like; whilst nothing was required to develop the picture but simply washing with hyposulphite of soda.

Another very efficient discovery of TALBOT's may be here recorded—namely, the property of gallic acid in rendering the prepared paper so sensible as to be capable of receiving impressions by instantaneous exposure, owing to the gallic acid of the ingredients continuing and developing the effect of the sun's rays. This agent was ultimately superseded by pyrogallie acid, introduced by ARCHER, the reducing or developing action of which is much greater than that of the gallic compound. Various methods for rendering paper sensitive to the reception of solar influence have been published, to dwell upon which would take up too much space. All, however, have their particular advantages, based upon the judicious application of the usual compounds, so as to produce a more even and more perfect coating with the silver salt.

Subsequent to the production of photographs on paper with considerable accuracy, glass was adopted for the basis of the picture; but as the sensitive media could not be made to adhere to this body alone, it was necessary to employ as an adjunct some adhesive matter. The first trials were with albumen—introduced by NIEPCE ST. VICTOR in 1848—and gelatin, laid in a thin stratum upon the clean surface of the glass. Iodide of potassium or alkaline chlorides were mixed with the adhesive composition; and after partial drying, the surfaces were exposed to solutions of nitrate of silver, when a sensitive coating formed on the film on which the picture was impressed. Generally, the pictures obtained on albumenized or gelatinized glass, owing to the even and close texture of the coating material, had many qualities superior to those produced upon paper, excepting where the practice of employing the latter waxed was followed. It was soon after the adoption of these materials by photographers, that ARCHER introduced pyrogallie acid, and soon after collodion, than which no other material is now more

extensively used. With the exception of modifications introduced from time to time to render the collodion film more sensitive, or to propagate the impression of the rays of light, and thus shorten the period of exposure, very little has been done within the last few years beyond rendering the art more general both in practice and application. Xyloidin, a compound prepared from starch with nitric acid, and tintured with iodine, was introduced a few years ago; but its use is not so extensive as that of collodion, notwithstanding its repute for being a more compact basis for the picture, and more capable of receiving the pictorial impression. The particulars of these methods will be detailed further on when describing the practice of photography. Besides the various progressive steps alluded to, there are a few others which tend to extend its usefulness, and deserve a short notice.

These are the methods for impressing colored pictures upon the prepared surface, and of engraving the photographic impression without the aid either of the artist's graver or pencil.

The latter, which might be called photogalvanography, is not recent, but almost as old as the first bituminous impressions of M. NIEPCE, whose finished pictures required but the application of the etching liquid to convert them into engravings. The system of procedure had been considerably improved by several others, more especially by NIEPCE the younger, LEREBOURS, and LEMERCIER, the latter applying it to lithographic printing. Dr. DORME of Paris endeavored to obtain engravings from daguerreotype plates by chemical agency, and partially succeeded. His method was to attack the plate with nitric acid before the gilding of the picture, when all the parts whereon the silver was reduced became more or less corroded according to the depth of shade. As nitric acid happened to be the agent used, it could not be always confined to the parts where its action should be manifested, and, therefore, the results were precarious. GROVE published a method for engraving the daguerrean image by voltaic agency in 1842; in this operation, the agent was chlorine liberated from hydrochloric acid, in which the picture, attached to the positive pole of the battery, was immersed. This method, though superior to its antecedents, was not all that was desired. A patent was granted in 1844 to FIZEAU and CLAUDET for engraving photographic impressions. Here hydrochloric acid, liberated from a mixture of chloride of sodium and nitrate of potassa, to which a little nitric acid had been added, was the etching medium, and ammonia and a hot concentrated solution of caustic potassa the auxiliaries to it in bringing the process to perfection—the former having the effect of removing the chloride of silver, and the latter protecting the surface coated with the mercury from the corroding action of the acid. When sufficiently deepened the plate was washed and dried, smeared with printers' ink, dried, cleaned, and the unetched parts gilded, after which the remaining parts could be deepened at will by first removing the ink. Another method discovered by H. F. TALBOT, and published by him in May, 1853, seemed to be most satisfactory. It consisted in coating a well-polished steel plate with a mixed gelatin

impregnated with a strong solution of bichromate of potassa; and, when dried, exposing this plate to the rays of light impinged from the illuminated subject in the camera; or, better, to the sun's rays, whilst a positive photographic picture had been laid upon it. As in the case of NIEPCE's bituminous method, so in this;—the influence of the light rendered the parts on which it fell insoluble, so that on subsequently washing in water the gelatin and bichromate solution were removed from the other parts, leaving a raised facsimile of the picture, the lights being represented by the bare metal, and the shades—corresponding to the lights in the original—by the altered gelatin. On pouring bichloride of platinum upon the washed surface, the plate became readily etched on the parts from which the gelatin was removed. When the action has been sufficiently continued, it is arrested by washing with a sponge, which removes the gelatin, and drying. The plate now exhibits a delicate etching of the picture on the steel plate, in which the raised surface corresponds to the light and half tones of the original design. PRETSCH of Vienna published a method for effecting the same purpose; it has much in common with TALBOT's, but instead of washing off the coating of gelatin, as directed by the latter, it is merely soaked in water, to swell the unaltered gelatin, and give the appearance of an engraved wood-block to the figure. An impression of the figure is then taken with a soft material in the way of a mould, and the latter is rendered a conductor of electricity, and copper is deposited upon it to any desired extent. In this way a true impression is taken of the photograph in copper, and may be multiplied at pleasure. Latterly, POITEVIN of Paris has used the same materials as TALBOT, and applied them to lithographic stone, and the results appear to be very satisfactory. Notwithstanding these several steps towards improvement, much still remains to be effected, both as to investigation and discovery, to give the art the utility which it is calculated to possess.

In color printing, or chromophotography, also, efforts have been made to impress the tints of the object upon the picture by chemical agency, but the results have not been as successful in this department as those just detailed of photogalvanography; still, sufficient indications have been given to show that the subject is feasible of attainment. In chromophotography, or heliochromy, as the process was called in France, BECQUEREL in 1854 and previously, showed that colors could be impressed on the picture at the instant of its formation, by employing the violet chloride of silver—a compound in which more or less of a basic chloride exists—for taking the picture. To give the subject more definition, he coated the silver plates by means of chlorine liberated from hydrochloric acid by voltaic agency, and in which solution the tablet was immersed, attached to the positive pole of the battery. As it was found that the shades were much altered by the thickness of the coating of the violet chloride on the plate, he introduced a voltameter of water in the circuit, to measure from the volume of hydrogen disengaged the quantity of chlorine set free, and by this means he was able to determine the quantity of gas that passed over a given extent of the plate. When a plate so prepared was

exposed in the camera to the solar light of the spectrum, all the chief colors were produced, beginning with the yellow and orange, and extending to the red and violet, thus leaving a colored picture. BECQUEREL observed that a temperature of 212° to 302° , applied to the plate before exposing it to the spectrum, or a heat of 97° kept up for two or three days, modified the strength of the colors, though giving good yellow and green impressions. As these hues could not be fixed so as to resist the effect of diffuse light, they were looked upon more as a scientific curiosity. NIEPCE St. VICTOR being led to infer a relationship between the color which many bodies communicate to flame, and that which light develops in a plate of silver coated as above, tried the effects of silver plates excited in chlorine water impregnated with various salts, such as chloride of strontium and the like, and placed the plate in the camera for the reception of the rays from colored bodies, when the image became impressed with the natural tints of the subject. Thus, an orange was obtained by the use of chloride of calcium, yellow by chloride of sodium or chlorine, red with chloride of strontium, green with boracic acid and chloride of nickel, and so on, employing for any particular shade a substance which similarly colors the alcoholic flame, or that of the blowpipe.

Mr. HILL of the United States had been engaged upon the same subject, and gave the public to infer that he had arrived at satisfactory results in obtaining colored photographs as early as 1850, by means of some chance composition of a nondescript nature; but though he has given details of the pictures he produced by this means, the Editor is unable to find any description of the method or substances which he employed. It is certain, however, that no sure means of impressing the hues of the natural bodies upon the daguerreotype or photograph have been yet arrived at; and notwithstanding the instances referred to, that the discovery of the process still remains a desideratum in the science and art of photography.

The art of photography is dependent partly on optics, and partly on chemistry. It is the business of the optician to provide a suitable camera in which the photographic tablet may be placed, and the image formed by the lens thrown upon it. It is the business of the chemist to prepare the sensitive tablet in a suitable manner to receive that image.

THE OPTICS OF PHOTOGRAPHY.—The simplest form of camera obscura is a dark box, having a small orifice in the centre of one end, and a focusing screen of ground glass at the other. On throwing a black cloth over the head and camera, and looking at the focusing screen, an inverted image is seen of the objects towards which the opening of the camera is presented. When the hole is large, this image is bright but indistinct; by reducing its size, the image becomes more distinct, but fainter. The brightness and size of the pictured objects depend upon the distance of the focusing screen from the hole; and the smaller that distance may be, the smaller are the objects and the brighter the picture. The shape of the aperture does not determine that of the picture or the outline of the objects, a triangular hole giving the

same image as a round one. The image formed in this simple camera, although more or less indistinct, is absolutely free from distortion, and the rules of plane perspective are strictly fulfilled.

To understand the principles on which the cameras are constructed, it must be remembered that every visible object of which an image can be formed by a lens, is supposed in optics to consist of an assemblage of luminous points, from each of which rays of light proceed in all directions, but without interfering with each other; and an assemblage of rays proceeding from any single point is called a *pencil*. A bright object, therefore, emits a pencil of light from each of the bright points composing it. Thus if A C—Fig. 403—be a piece of brass wire, the several points of it, A, B, C, emit each a pencil of light—not a single ray—and these pencils do not interfere with each other. To illustrate this further, let E F—Fig. 404—be the object, B C the camera, L the hole, and K D the focusing screen; then a pencil of light proceeding from E passes through the hole L, and the rays continue to diverge until they reach the focusing screen at e, at which point a spot of light is produced of the same shape as the hole at L, but somewhat larger than it, and of the same color as the point E of the object. Similarly the points F, G, H, I, *et cetera*, emit pencils which after passing through the hole illu-

Fig. 403.

Fig. 404.

minate the spots at *f, g, h, i, et cetera*, and in this way an indistinct inverted image of the object is formed. The size and shape of the image do not depend upon the opening, because the luminous points of the object being infinite in number, and in close juxtaposition, the spots of light which compose the image, although individually of the same shape as the holes, glide one into the other, and form a continuous outline, in which all trace of the form of any particular spot is destroyed.

To show that the image upon the focusing screen is a correct perspective view of the object, the following illustration is submitted:—Suppose that L—Fig. 405—is the eye of a spectator, which is considered to be a mathematical point, and that straight lines, called *visual rays*, are drawn from L to the several points of the object E F; these straight lines constitute the edges of a system of pyramids, of which L is the common vertex, and if these are cut by any vertical plane at N between L and the object, the section is a plane perspective view. This is the fundamental definition of a plane perspective view. Now, let it be supposed that the visual rays are produced through L, so as to

form another system of pyramids on the opposite side of it; it is evident that if this second system be cut by a plane at M parallel to that at N , and at an equal distance

from L , the inverted image thus formed would be an exactly equal and similar geometrical figure to the image at N , and the two figures would coincide if one were laid against the other. But the image at M , is that which would be formed by a camera having a hole at L , and a focusing screen at M ; so that this simple camera gives a correct perspective view of the object as seen from the aperture, and depicted upon a plane surface as far in front of the hole as the focusing screen behind it.

The great defect of the image produced in the simple camera is, its indistinctness, because the pencils have no foci or point of concurrence of the rays. In order to remedy this evil convex lenses, or convex combinations of lenses, are introduced and placed at L .

The simplest form of lenticular camera is that in which a very small convex lens is placed at L —Fig. 406. A direct pencil diverging from a point, c , of an object is then, after refraction through the lens, brought to a focus at e , where a distinct image is formed; but the

oblique pencils from points A , B , are brought approximately to foci at points a , b , upon a circular arc, of which L is the centre, and Lc the radius, and the rays after passing through the points, a , b , again diverge and produce round spots or discs of light upon the screen, instead of a sharp focus as at e ; the true image of the object being curved, as shown in the figure. A small single lens, therefore, gives so much curvature of the image as to render its margin very indistinct compared with the centre. It will be observed, however, that the image formed by a small single lens is free from distortion, because the axes of the pencils do not suffer deviation by passing through it.

In order to increase the radius of curvature of the image, the following plan has been adopted in the lenses used by photographers for taking *views*; in these the light enters through a small aperture, and the time of exposure is a matter of less consequence than obtaining a picture uniformly sharp to the edges. Instead of placing a small lens at L , a large one is fixed at some distance behind L , as in Fig. 407. A central pencil from c is refracted through the centre, m , of this lens,

and an oblique one from A , after passing through the hole at L , is refracted near its circumference at n . This renders the image much flatter; because the distance, na , which is equal to the focal length, mc , of the lens, is measured from n and not from m , as in the case of a single lens placed at L . But this arrangement is open to the very serious objection, that the image is greatly distorted, in consequence of the axes of the oblique pencils being bent out of their course by refraction through the circumference of the lens, which acts as a prism in causing rays to deviate from its edges, and, therefore the marginal parts of the image are too small for the central; besides, all straight lines in the image which do not pass through the centre are curved inwards at their extre-

mities; so that in this form of view-lens, flatness of field is gained at the sacrifice of true perspective.

The form of this lens is meniscus, or concavo-convex, the concave side being turned towards the objects; and the radius of curvature of the image is equal to the focal length of the lens, plus the radius of its convex surface; it is, therefore, longer by the latter quantity than the radius of curvature of the image formed by a small single lens without a diaphragm in front.

All photographic lenses require to be achromatized, or so constructed as to refract the different colors equally, in such a way that the yellow and violet foci may coincide; because the yellow rays produce the *visible image*, while all the rays of the spectrum which lie between the green and the extreme lavender produce more or less chemical effect upon the sensitive photographic tablet. The common view-lens is an achromatic meniscus, and it may be achromatized in two different ways, one of which consists in placing a double

concave lens of flint-glass before and in contact with a double convex lens of crown-glass, as shown in Fig. 408; and the other, in placing a concavo-convex lens of crown-glass before and in contact with a concavo-convex lens of flint-glass, as shown in Fig. 409. The

effect of these combinations arises from the circumstance, that flint-glass and crown-glass possess very different powers of *dispersing* or of separating the rays of light.

In the preceding Figs., *c* denotes crown, *f* flint-glass. Both forms have equal radii of the front and back surfaces, equal focal lengths, equal curvature of the image, and an equal distortion; but the plan shown in Fig. 409 is the best, because there is rather less spherical aberration. Even this is very bad, and should be superseded by the view-lens, which has recently been invented by Professor PETZVAL, and which will be described presently.

The best form of *view-lens* for giving pictures entirely free from distortion is a combination of two achromatic plano-convex lenses, with the convex sides outwards, and a small stop midway between them, as shown in Fig. 410. If a ray, *PQ*, be refracted

through this combination in such a way that its course between the lenses passes through the centre of the stop, it is evident, from the symmetry of the figure, that the emergent ray, *RS*, will be parallel to *PQ*; from which it follows that the axes of pencils refracted through this combination do not suffer deviation, and therefore there is no distortion in the image. The curvature of the image is, however, greater than with the single view-lens, and the central definition, when the diaphragm is removed, not quite so good as that of the *portrait-lens* to be described presently.

The best view-lens for combining tolerable freedom from distortion, with flatness of field and perfection of focus—that is to say, the most generally useful view-lens is that of Professor PETZVAL of Vienna, and commonly called the *orthoscopic lens*, from the fact that the straight lines of objects are not curved in the

image. Its construction is shown in Fig. 411. The front lens is achromatic and convexo-concave; and the back lens achromatic, and composed of two,

which only touch at the edges. The inner one—that is, the one next to the front lens—is of crown-glass and double concave, with the deepest concavity next to the meniscus; the outer one is a meniscus of flint-glass. The front lens of the combination is convex, and brings rays to a focus; the back lens is concave, and scatters them. In order to improve the definition, and bring objects at different distances into good focus, a stop is placed immediately behind the back

lens. The distance between the front and back lenses of the combination is about equal to half the diameter of the front lens, and the diameter of the back lens is about two-thirds that of the front one. In this combination the oblique pencils pass near the circumference of the front, and through the centre of the back lens; they are therefore lengthened, and the consequence is the production of a very flat field. A small amount of distortion is produced by this instrument, which causes straight lines not passing through the centre of the picture to be curved *outwards* at their extremities, and the objects at the margin of the field are rendered proportionally larger than those in the centre; but these defects exist to a much smaller extent than those of an opposite kind in the single view-lens.

There are, therefore, three different view-lenses used by photographers, namely—the single view-lens, with a stop in front, which gives a flat field, but great distortion; the symmetrical double combination, which gives an image entirely free from distortion, but having considerable curvature; and the orthoscopic combination of PETZVAL, which gives a tolerably flat field, and the image *nearly* free from distortion. The second lens is the best when a sufficiently small stop can be used to obtain good marginal definition. In other cases the orthoscopic lens is the best, and the single view-lens the worst.

The view-lens includes an angle of from 35° to 40°. It cannot be used for portraits in a glass room, because it would require too long an exposure.

The *portrait-lens* commonly used is that which was invented by Professor PETZVAL about seventeen years ago. In this combination everything is sacrificed to getting a large central pencil free from spherical and chromatic aberration. The curvature of the image is considerable, and the angular field of view rarely exceeds 20°. Its only merit is quickness of action, which is absolutely required in photographic portraiture. As soon, however, as more rapid processes are discovered, the portrait-lens, with its large aperture and many unavoidable defects, may be given up.

The construction of the portrait combination of PETZVAL is shown in Fig. 412. The front lens is

achromatic and convexo-concave, the lenses being in contact. The back lens is achromatic, and formed of two lenses separated by a small interval; the inner one is of flint-glass, and convexo-concave, the outer one of crown-glass, and double convex, with the flatter side outwards. The focal lengths of the two compound lenses are nearly equal, the front lens having the longer

focus, and both are convex lenses. The combined focal length of the instrument, measured from the back one, is from three to four times the diameter of the front lens. Sometimes, when the light is strong, or it is required to take objects out of doors, a stop is used. This should be inserted between the lenses, and the proper place for it must be determined by trial. If placed too near the front lens the image of a perpendicular straight line brought to the margin of the focusing screen is bent *inwards* at the extremities, and if placed too near to the back lens, *outwards*; there is an intermediate point where the image is perfectly straight, and that is the proper place for the stop. In mounting lenses care should be taken to exclude stray light, and to prevent reflections from the inside of the tube, and the outside edge of the lenses by blackening the interior.

THE CHEMISTRY OF PHOTOGRAPHY.—In this department of the art, the principle involved is the production of a saline surface which is capable of being modified by the actinic or chemical rays in light, the development of this action by chemical means, and finally its fixation, by removing all matter which is capable of further change by the agency that produces the picture. The substances which are pre-eminently employed in this art are the various salts of silver, more especially the chloride, iodide, and bromide of this metal. Besides these, there are other compounds which are capable of being acted upon in a similar manner, and consequently give, under proper treatment, impressions of objects; such, for instance, are compounds of gold, uranium, chromium, and other easily reducible substances. It is well known to every chemical student that a silver salt, such as the chloride, iodide, bromide, phosphate, and the like, when freshly precipitated and presented to the sun's rays, rapidly assumes a purplish hue, and finally turns black. So, also, in regard to compounds of gold, uranium, or chromium, an effect is observed when these are exposed in very thin layers, that shows a chemical action has taken place. In all these cases where diffuse light makes an impression, the effect is due either to a reduction of the salt to one of a more basic nature, or to the isolation of the metal from the salifiable body. For example, supposing a surface coated with a thin layer of chloride of silver be exposed to the light of the sun for a short time, the resulting darkening of the pure white of the salt is due to an abstraction of part of the chlorine from it; if its exposure be continued the change gradually progresses, till finally the compound will contain no chlorine, or at best but a very small portion. To illustrate this, if the chloride of silver be represented by Ag Cl , the effect of the chemical action of the actinism or chemical principle in light may be expressed by the formula—

that is, two equivalents of the silver salt will evolve one equivalent of their chlorine when water is absent, or one of oxygen when water is present. By continuing the reducing effect of the light, the chlorine ultimately is entirely separated, and only finely-divided metal remains. The latter change is, however, rarely

effected in the ordinary practice of the photographer. As with silver, so with gold and the other substances alluded to; they all lose a portion of their salifying element, and thus acquire a composition different from what they originally possessed, becoming by such metamorphoses more permanent under radiant influences.

In photographic practice, the action of the light is propagated by other chemical compounds, generally those which have a great affinity for oxygen, and by assimilating which they pass into a higher state of oxidation. Such are the various preparations of the protoxide of iron, protosalts of tin, and formic and other organic acids that are capable of assimilating oxygen from metallic salts. Hence the practice of *developing* the image incipiently formed by the light with a protosalt of iron, or any of the other compounds just alluded to. Besides these, another process of a chemical nature is required to give permanency to the impression produced by the combined agency—by the impinged rays and the reducing agent—and which has for its object the removal of the sensitive salt from the parts which form the lights in the positive and the shadows in the negative pictures, presently to be described in the practical details of the art. The agents used for this purpose are water, hyposulphite of soda, $\text{NaO S}_2 \text{O}_2$, ammonia, cyanide of potassium, and a few other compounds capable of dissolving the metallic combinations employed for the basis of the picture. After bringing these chemical processes to bear upon the production of a photographic picture, nothing further is necessary beyond the few simple operations of drying and mounting.

The chemical principles that govern the art will be more fully enlarged upon in the description of the practical details of the several processes, and which, for the sake of clearness, will be divided into the daguerreotype, the collodion, the albumino-collodion, the calotype, the photogenic and printing processes, to which will be added the application of photography to other branches of art, such as photolithographic, photoglyphic, and photogalvanographic operations.

PRACTICE OF PHOTOGRAPHY.—Before immediately entering upon a detail of working, it may be well to remark that in the images formed in the camera obscura the lights and shades are true to nature, but the position of objects is reversed, as regards right and left. In fixing these images by photography upon various tablets, the object is to produce impressions true to nature in the lights and shades, and non-reversed.

There are two ways of doing this. According to one method a *negative* photograph is first produced, from which, by a second photographic process, a *positive* photograph is obtained. The other method consists in obtaining a positive photograph by one operation.

By a *negative* is meant a transparent photograph in which the lights and shades are the opposite to those in nature, and the objects reversed as regards right and left. By a *positive* is meant a photograph in which the lights and shades are true to nature.

Two direct positive processes are commonly used; they are called the *daguerreotype* and the *positive collodion* processes. In the former the picture is

produced upon a silvered copper plate; in the latter upon glass, or some black even substance, such as glazed leather, oil-cloth, enamelled iron, *et cetera*.

THE DAGUERRETYPE PROCESS.—This process is now hardly ever practised in Great Britain, and but partially in America; nevertheless, a short description of it will not be uninteresting:—A silvered copper plate is first polished to the utmost; it is then rendered sensitive to light, by being exposed to the fumes of iodine and bromine, after which it is presented to the image in the camera; no visible picture is produced until the plate is submitted to the vapor of mercury, which adheres only to the parts that have been acted on by light, thus forming the lights of the picture, whilst the blackened polished metal forms the shadows. The subsequent operations consist, first, in removing the film of argentine, iodide, and bromide from the plate by immersing it in a solution of hyposulphite of soda, and next in fixing the picture permanently to the plate by means of a boiling solution of *sel d'or*—hyposulphite of gold and soda—which at the same time greatly improves the appearance of the picture. Such is a brief sketch of this very beautiful process. It now remains to describe the operations more in detail.

To Polish the Plate.—The plates are polished by dusting a little finely-powdered rotten-stone upon them, and rubbing them all over with a little cotton or fine flannel dipped in a solution of nitric acid in twenty parts of water. When all dirt is removed, they are dried by friction with fine dry cotton or flannel. Finally, the slight scratches produced in the first operation are effaced by rubbing the plates on pads of velvetreen nailed to a board, and upon which powdered charcoal of different degrees of fineness is laid. When perfectly clean and polished, the breath should condense upon it in an even sheet.

To Excite the Plate.—Two coating boxes are required for this operation, one to contain iodine, the other lime saturated with bromine. Those with glass pans are the best. The iodine is spread evenly over the bottom of one of these boxes, and the bromide of lime to the depth of an inch over the bottom of the other. The plate is then laid with its face downwards over the iodine, for a minute or two, until it assumes a deep yellow color; it is then removed, and laid over the bromine for a minute, or until it assumes a bluish steel color; and then again over the iodine for a few seconds, after which it is ready to be exposed in the camera. In exposing the plates to the exciting media, the time of exposure must necessarily be dependant on the temperature of the room, and consequently, there is nothing to direct the operator, except the tint of color on the polished surface mentioned above. The plate may be examined under a feeble light, until it is put over the iodine the second time; and should any accident occur in taking a picture, and the plate be exposed to light, there will be no necessity to clean and excite it again; for the mere exposure to iodine for two or three seconds will obliterate the impression, and render the plate in as good condition for receiving a fresh impression as it was before.

The Exposure in the Camera.—The exposure in the camera and development of the image should follow

the exciting of the plate as quickly as possible; nevertheless, if the sensitive plates be put into a closely-covered plate box, face to face, they preserve their sensitiveness for some hours unimpaired.

The time of exposure in the camera is a matter of critical importance, and it can only be ascertained to great nicety by experiment. The process is exceedingly sensitive and rapid, and with the full aperture of a portrait-lens, and a strong light out-of-doors, an instantaneous exposure is sufficient; but under glass, and with only a moderate diffused light, several seconds are required, and sometimes with a view-lens and small diaphragm several minutes; much of course depending upon the brightness of the object and the size of the diaphragm.

The over-exposed parts of a picture look blue, and are said to be *solarized*. The under-exposed parts appear black and devoid of detail. The photographer should avoid as much as possible too violent contrasts of light and shade in the model, and aim at half tone and modulation of shade; and in exposing a plate, the exposure should be timed with reference to the shadows, and the lights left to take care of themselves. There are differences of opinion with respect to the comparative sensitiveness of the daguerreotype and collodion processes, but the positive collodion process is generally believed to be the more sensitive of the two.

The Development of the Image.—On removing the plate from the camera, it is placed in a mercury box containing the vapor of mercury heated to about 140°. The most convenient mercury box is that used in America; it is made of iron, and shaped like an inverted pyramid, the mercury being at the bottom, and the plate laid horizontally over it. It is provided with a thermometer which indicates the temperature, and the mercury is heated by a spirit-lamp placed underneath. The surface of the mercury should be perfectly clean; and it will frequently require filtering either by squeezing through a wash-leather, or passing through a glass filter with a small aperture made for the purpose. The time of development depends upon the size of the box, the temperature, and the quantity of quicksilver used, and it may vary from two or three minutes to a quarter of an hour—about five minutes is a good average time. The development should not be stopped until all the details in the shadows are fully out. If continued too long, or if the mercury be too hot, the picture appears hazy, the shadows assuming a peculiar speckled appearance.

The Fixing and Gilding.—On removal from the mercury box, the picture may be exposed to daylight, as no further development can take place. In order to remove the iodine and bromine from the plate, it must be immersed in a solution of hyposulphite of soda in distilled water. The strength is immaterial; one part hyposulphite to six parts of water will do very well, but it is important always to filter the solution through blotting paper. It should be poured into a flat dish, and the plate immersed face upwards in such a way as that a wave of liquid flows quickly over it, and two waves not allowed to meet upon it in any part. The yellow film upon the plate is now quickly cleared off, and the polished silver with the grey image upon it

exposed to view. The plate must then be well washed with distilled water, drained, and laid accurately horizontal upon a levelling stand, ready for the operation of gilding. This is accomplished by pouring upon the plate through a funnel, having a tuft of cotton wool in its neck, as much of a solution of hyposulphite of gold and soda—*sel d'or*—as it will hold without any running over, and then heating this liquid to the boiling point by passing a spirit-lamp backwards and forwards under the plate. The *sel d'or* solution is made by dissolving half a grain of the compound hyposulphite in an ounce of distilled water. While boiling the solution upon the plate, bubbles form but must not be allowed to stick to it; this is prevented by tapping the foot of the levelling stand occasionally with the bottom of the spirit-lamp, and thus communicating a vibration to the plate. As soon as the liquid becomes hot, the lights of the picture darken; but after a few seconds they begin to get whiter, and the blacks blacker. In the course of a minute or two, the appearance of the picture is greatly improved, and the process is then arrested by pouring off the hot liquid, and washing the plate with cold distilled water poured over it from a bottle having a glass tube fitted into the cork; after which it only remains to dry the plate, and the picture is finished. This is done by taking the corner of it in a pair of pincers, holding it at an angle of about 45° to the floor, and passing the flame of a spirit-lamp underneath, beginning with the upper corner, chasing the line of wet from the upper to the lower corner, and removing the last drop with blotting paper.

The rationale of the daguerreotype may be inferred from what has been said under the chemistry of photography. A film of iodide and bromide of silver, sensitive to light, results from the exposures in the exciting boxes. This attenuated coating is reduced by the chemical rays of the light impinged upon it, to the state of a subsalt; and upon exposure to the mercurial vapor the metal deposits upon the part so attacked. All the unaffected argentine surface is deprived of the sensitive iodo-bromide of silver by the solution of alkaline hyposulphite—and the final treatment with gold solution has the effect of depositing the gold by electrolysis upon the parts of the plate acted upon by the light.

The daguerreotype process may be considered the most perfect of all the photographic processes at present known; for certainly it stands unequalled for microscopic perfection of detail, modulation of shade, and beauty of half-tone; nor is this superiority to be wondered at when it is considered that the chemicals are applied in the form of impalpable vapor, and that the tablet is a highly polished metal plate; while in other processes the chemicals are either contained in a coarse material like paper, or else in a gummy film, which is spread upon glass, leather, or enamel.

Daguerreotypes are permanent when the manipulation is properly performed, the plate thoroughly washed, and carefully sealed up in an air-tight case. In order to avoid the reversion of the image, a reflector must be used in front of the lens, an expedient which is not necessary in any other process.

THE COLLODION PROCESSES, POSITIVE AND NEGATIVE.—Collodion, so named from its adhesive nature, is a gelatinous substance made by dissolving pyroxylin—gun-cotton—in a mixture of ether and alcohol. It is extensively used in photography, as a vehicle for supporting the sensitive chemicals.

The reader will find a detailed account of the methods followed in the preparation of gun-cotton, or pyroxylin, *ante* Vol. II., page 329, and a brief description of the process for converting this material into collodion at page 334. It may be convenient, however, to repeat shortly in this place, the process of making plain collodion with a special view to its application for photographic purposes:—Mix together in a large and perfectly dry basin equal parts, by measure, of commercial oil of vitriol and nitric acid, specific gravity 1.42. The temperature of the mixed acids rises to about 150°; and it must be maintained at that temperature by placing the basin in hot water, if necessary. The operation must be conducted under a chimney in order that the fumes may escape. Then immerse in the mixture, in small quantities at a time, the best cotton wool, such as is manufactured for chemical purposes, pulled out into thin flat pieces. Put as much into the liquid as it will conveniently cover, and stir it about with two thick glass rods for the space of five minutes. Then pour the whole contents of the basin into an earthenware colander, so that the acids may drain off, and wash the cotton thoroughly by putting it for a minute under a tap; after which throw it into a pail of water and stir it about with the glass rods. Change the water, and continue this washing for some minutes, squeezing the gun-cotton between the hands occasionally; and, lastly, put it into warm water, to which a little soda has been added, in order to neutralize completely all trace of acidity; after which wash the gun-cotton again thoroughly in several changes of water, and let it soak in water for an hour or two; then remove it, squeeze it, and spread it out to dry spontaneously in a safe place, or hang it up to dry in a net suspended from the ceiling. When nearly dry pull it out into small pieces or tufts, and in this state let it get thoroughly dry. It should then be put away in a tin canister. It is an exceedingly inflammable and dangerous substance, and has been known to decompose by keeping, and evolve dense suffocating fumes. Great care should therefore be taken in the manufacture and preservation of gun-cotton.

The proper strength of the nitric acid should be strictly observed; for there are several kinds of gun-cotton, some of which are quite unsuitable for the purpose. For instance, if the strongest nitric acid is used, specific gravity 1.5, the gun-cotton is of the most explosive kind, and will not dissolve in ether and alcohol; if, on the other hand, the nitric acid be too weak, the gun-cotton is but imperfectly soluble, and a good deal of it becomes disintegrated, and is lost in the washing. But even supposing the gun-cotton to dissolve perfectly in the ether and alcohol, the collodion may still be faulty; for if the acids are too strong, the collodion film when spread upon a glass plate contracts greatly on drying, and if too weak, the film is opalescent, and partially opaque like tissue paper, instead of

being transparent and structureless. Then, again, the temperature of the acid mixture is a matter of importance; for if it be too low, the negatives are deficient in density; and if too high, the collodion becomes insensitive, and fails to give the half-tones of the picture—the blacks assuming excessive density, while the lights remain clear and devoid of detail. On the whole, the best proportions, strength, and temperature of the acid mixture appear to be those indicated in the former paragraph.

Having thus shown how to make photographic pyroxylin, it remains to describe the mode of dissolving it in a mixture of ether and alcohol, so as to produce *plain collodion*. This is done as follows:—Mix together absolute ether, specific gravity .725, one part by measure, and absolute alcohol, specific gravity .800, three parts by measure; and to every fluid ounce of this mixture add from six to eight grains of pyroxylin, according to the thickness of film required. Shake the mixture well for some minutes. The pyroxylin quickly dissolves. The bottle should then be put aside and remain undisturbed for several days, at the end of which time the clear liquid may be drawn off by means of a siphon from any sediment which may form, and it is then ready for use. The ether and alcohol employed may be either pure or methylated. *Absolute* methylic ether and alcohol appear to answer the purpose exceedingly well, and are much cheaper than pure spirits, since they pay no duty. They have also this advantage, that the iodized collodion does not become so quickly deteriorated as when pure spirits are used.

For making collodion, the following proportions by weight have also been severally recommended:—

Gun-cotton,	1	...	5	...	1
Ether,	120	...	110	...	196
Alcohol,	60	...	20	...	12

Whatever be the quantity of the fluids taken to dissolve the cotton originally, the solution, if too thick, can be easily diluted to the suitable degree. This is known by pouring a small portion of it on a plate of glass, on which it should flow freely, and leave at the same time a firm film of collodion, and so cohesive as not to break under a stream of water. Any fibres of the cotton that may remain undissolved may be separated by filtration. DELAMOTTE and others add a few drops of ammonia to the bulk of the collodion to prevent acidity.

To iodize the collodion many receipts are followed. ARCHER's method is to make a saturated solution of iodide of potassium in alcohol, and to add as much iodide of silver as the liquid will dissolve, even with repeated shakings, and, after the menstruum clarifies, to add a sufficient quantity to enable it to take up a coating of silver from the argentiferous bath. Generally the iodizing solution is made differently for positives and negatives. For negatives it is made by dissolving fourteen grains of iodide of potassium to the ounce of alcohol, specific gravity .825; for positives by dissolving ten grains of iodide of potassium and two grains of bromide of potassium to the ounce of alcohol, specific gravity .825. In order to iodize the collodion, one part by measure of the iodizing solution is added to three parts by measure of the

plain collodion. The mixture is shaken well together, and may be used at once.

Sometimes iodide of ammonium and fluoride of potassium are used for positive pictures, in the proportion of forty-two grains of the iodide and two of the potassium salt to six ounces of the collodion. The two salts are put into the sized bottle specified, and five or six drops of water added to moisten, but not to completely dissolve them, and the plain collodion afterwards added. On shaking the whole, and allowing it afterwards to rest, complete solution will take place. The following are other proportions which work well:—

Collodion,	6 ounces.
Iodide of ammonium,	53 grains.
Fluoride of potassium,	2 grains.
Water,	5 drops.
Collodion,	6 ounces.
Iodide of potassium,	12 grains.
Iodide of silver,	7 to 8 grains.

When methylated spirit is used, and the gun-cotton properly washed, the iodized collodion remains colorless; but when pure spirit is employed, it turns at once of a pale yellow color, which gradually deepens by keeping to an orange-yellow, and ultimately to a deep red; the collodion is then insensitive and useless.

The bottle containing plain collodion should never be shaken, and the iodizing solution should be filtered through blotting paper. The iodides of cadmium or ammonium are liable to objections, for the salts of cadmium impair the fluidity of the collodion and put the nitrate-bath out of order, while the salts of ammonium are exceedingly unstable. Collodion iodized with iodide of cadmium does not become discolored by keeping; but, although not visibly deteriorated, its good qualities are nevertheless impaired.

THE NEGATIVE COLLODION PROCESS.—The operations for taking negative collodion pictures consist in cleaning the glass plate, coating it with iodized collodion, rendering it sensitive by immersion in the nitrate of silver bath, exposing it in the camera, developing the latent image, removing the redundant chemicals, and washing, drying, and varnishing the picture.

Patent plate-glass should be employed for negatives; because plates of flatted crown or common window-glass, not being perfectly level, are liable to get broken in the operation of printing. The edges of the plates should be ground by rubbing them in a notch made in a piece of stone.

To Clean the Glass Plates.—Wash them well with water, and scrub them with a hard brush till they appear to be clean. Then rub them all over with a tuft of tow dipped in dilute nitric acid; wash them again thoroughly in several changes of water, or under a tap, wipe them dry with clean linen cloths, and finally polish them with a washleather or piece of cambric. When a plate is perfectly clean, the breath condenses upon it in an even sheet free from irregular markings.

To Apply the Collodion.—Hold the plate horizontally by one corner in the left hand, or put it upon a plateholder, blow off any dust that may have settled upon it, and pour in the centre of it a circular patch of collodion rather more than half as large as the plate. Then tilt the plate so as to allow the collodion to run

towards the thumb, but without actually touching it, and afterwards to the adjacent corners, and pour off the surplus from the corner diagonally opposite to that by which the plate is held, into the bottle. After which rock the plate backwards and forwards with the corner upon the neck of the bottle, so as to prevent the formation of lines in the collodion, and place it upon the dipper of a nitrate-bath, where it may remain from one to five minutes according to the temperature. It is now ready to be excited.

To Excite the Collodion Film.—This is done by immersing the plate, as soon as the film has set, in a bath of nitrate of silver, made by dissolving thirty grains of pure nitrate of silver to the ounce of distilled water. The bath should be an upright vessel, of glass or porcelain, and moulded in one piece. Gutta-percha is frequently employed; but although very good for the purpose, it is hardly so trustworthy as glass, and some operators have complained of gutta-percha baths communicating impurities to the nitrate-bath, and putting it out of order. The plate should be completely immersed without pausing, as that would occasion a line across it. It should remain in the bath during a minute, moved up and down two or three times to take the ether from its surface, and allow an even coating of the silver salt to be formed. After this it is permitted to remain during two or three minutes longer according to the temperature and the strength of the bath. Three minutes suffice when the bath is at 60° to 65°. The film will now exhibit an even coating of yellow iodide of silver. It should be drained for a few seconds over the bath, the back of it wiped with blotting paper, and then put into the dark slide.

It is important that the nitrate-bath be made with pure nitrate of silver, obtained by dissolving silver in pure nitric acid. When common commercial nitrate of silver is used, it is impossible to obtain good results with certainty and uniformity, and it generally becomes necessary to add acetate of silver to the bath in order to obtain sufficient density in the blacks. When the nitrate of silver is pure, and nearly all the free nitric acid got rid of by redissolving and recrystallizing it, the bath works well without any additions. It gradually acquires iodide of silver, nitrate of potassa, and organic impurities by use.

It may be remarked that by leaving the plate in the bath longer than is requisite, and when the collodion is tender, or has been introduced before it has sufficiently dried and acquired proper tenacity, it frequently cracks and drops in fragments into the bath. If the collodion be good and moderately old, the excited plate possessing an opal hue suffers no injury by remaining a little longer immersed; but when the bath is fresh, it should be taken out as soon as it becomes sufficiently excited, otherwise the iodide on the plate will be attacked. Some photographers obviate this inconvenience by adding about one grain of iodide of silver to the ounce measure of silver solution.

The Exposure in the Camera.—This is a point on which it is impossible to give exact directions; but the faults due to over and under-exposure may be clearly pointed out. In an under-exposed picture the details of the shadows cannot be brought out, and the

blacks acquire excessive opacity. In an over-exposed picture the details of the shadows appear before the blacks have had time to become sufficiently intense; and, since the development cannot then be sufficiently prolonged, the result is a flat feeble picture, deficient in contrasts.

The proper time of exposure depends on the aperture of the lens and its focal length, and it varies *directly* as the square of the focal length, and *inversely* as the square of the diameter of the aperture, when different lenses are employed. By the focal length is meant the distance of the *focus*, or point of convergence of the rays, from the centre of the lens; that is, the distance at which the image on the screen appears quite distinct.

To Develop the Latent Image.—Hold the plate in the left hand by one corner, or place it upon a leveling stand, and pour over it a sufficient quantity to cover it, of either of the following mixtures:—

	Hunt's.	Delamotte's.
Pyrogallic acid,	1 grain...	5 grains... 9 grains.
Water,	1 ounce..	10 ounces.. 3 ounces.
Glacial acetic acid, ..	1 scruple.	40 drops... 2 drachms.

In a minute or less the dark parts of the image appear, and are soon followed by the half tones and finer details in the shadows. Let the developer flow backwards and forwards over the plate until the picture is fully out, and sufficiently dense. If the collodion is good, and the nitrate bath in good order, the development need not be hurried, but may occupy several minutes. Under some circumstances it may be well to add a few drops of solution of nitrate of silver to the developer in a measure, and pour it again over the plate, in order to give the blacks greater intensity.

When the negative is fully out in all its details, wash it well with water.

Some persons use a developer composed of protosulphate of iron, thus:—

Distilled water,	1 ounce.
Protosulphate of iron,	5 grains or more.
Acetic acid,	5 minims or more.

A shorter exposure will then suffice, and the contrasts of white and black are less violent, and half tones prevail to a greater extent. The mode of treatment is the same as with pyrogallic acid. Nitrate of the protoxide of iron is sometimes substituted for the sulphate.

To Fix and Finish the Picture.—When the plate has been well washed after the development, by pouring water over it from a jug, the yellow iodide of silver should be dissolved out by means of either a saturated solution of hyposulphite of soda, or a solution of cyanide of potassium—strength about five grains to the ounce of water. This should be poured over the plate, and should be allowed to run backwards and forwards over it until the whole of the yellow iodide of silver in the plate has disappeared; after which it should be thoroughly well washed, by pouring water over it from a jug, and set up to drain and dry; or it may be dried before a fire. It is then ready to be varnished.

The best kind of varnish to apply to a cold plate is made by dissolving powdered dammara resin in benzol. This is poured over the picture in the same way as the collodion on the plate. It dries in a few minutes. But a better varnish, used with a heated plate, is made by dissolving shell-lac in alcohol. This is called spirit varnish. Before applying it, the plate should be heated before a fire to about 100°, and after applying it, to about 150°. When dry, this varnish is extremely hard and difficult to scratch, and it protects the picture effectually from injury in printing.

The negative is now finished. An unlimited number of prints may be taken from it, by the printing process.

THE POSITIVE COLLODION PROCESS.—A collodion negative is intended to be looked *through*; a collodion positive to be looked *at*. A negative must possess density when looked through, and the color of the surface deposit is of no consequence. A positive need not possess density when looked through, and the color of the surface deposit is of great consequence, for it should be white. Hence the difference between the processes. Now it is found that organic matter combined with the silver of the image gives density and a bad surface color; while the absence of organic matter gives a good surface color, but no density. It is evident, therefore, that in the positive process an inorganic developer, such as protosulphate of iron, must be used instead of pyrogallie acid, which is an organic substance; while the nitrate bath should be acidified with nitric, and not with acetic acid. Bearing these things in mind, the processes become nearly identical in manipulation; the only difference being, that in the development of positives, the operation is much quicker, since it is only a superficial indication of detail that is wanted, and not density.

A positive is true to nature, because wherever the light acts a white precipitate of metallic silver is formed; while the parts where light does not act remain clear glass, and these are converted into dense blacks by simply applying black varnish to the back of the glass.

The nitrate-bath for positives is composed of—

Distilled water,	1 ounce.
Nitrate of silver,	40 grains.
Nitric acid,	1 minim.

The developer is made thus:—Dissolve one ounce of powdered nitrate of baryta in sixteen ounces of boiling distilled water, and when cold, add two drachms of nitric acid, specific gravity 1.42. Next add one ounce and a half of powdered protosulphate of iron. Shake well until the iron salt is dissolved. The mixture becomes white and turbid, in consequence of the formation of sulphate of baryta. Let this settle to the bottom of the bottle, and then decant and filter the clear liquid, which is of a green color, and is a mixture of protonitrate and protosulphate of iron. Add two ounces of alcohol to make it flow better over the collodion film. It is now ready for use. It deteriorates by keeping, and acts much better when fresh.

One ounce of protosulphate of iron decomposes

about one ounce of nitrate of baryta, forming insoluble sulphate of baryta, and soluble protonitrate of iron. The remaining half ounce of undecomposed protosulphate of iron forms the energetic part of the developer.

The nitric acid should be added to the nitrate of baryta, and not after the addition of the iron salt, as some sesquioxidation of the iron might then occur, which would occasion a browning of the solution, and cause a precipitate.

Some operators use nitrate of potassa instead of nitrate of baryta, but this is not right, because the sulphate of potassa formed is soluble, and remains in the solution, while the sulphate of baryta, being insoluble, can be removed. The use of acetic acid instead of nitric acid, is also wrong, because it injures the color of the whites, being an organic substance.

The development of a positive only occupies a few seconds, and it must be stopped as soon as there is the faintest indication of the details in the shadows. The plate should then be well washed to remove all traces of iron, and the picture fixed with a liquid composed of:

	Parts.
Water,	60
Cyanide of potassium,	6
Nitrate of silver,	1

The picture should be fixed with cyanide of potassium, and not with hyposulphite of soda, for two reasons;—first, because the cyanide removes more perfectly any organic compound of silver which might injure the color of the picture; and, secondly, because the hyposulphite of soda injures the color by blackening the silver.

A black ground may be given to the picture, either by backing the plate with velvet, or by passing upon it black varnish. This is made by dissolving asphaltum in benzol, and adding a little india-rubber to prevent it from cracking, a fault to which it is very liable. Printers' ink makes a good varnish, which does not crack. To apply it, rub it upon the back of the glass, and also upon a piece of paper, and then press the blackened side of the paper against the blackened side of the glass, and put the picture at once into its case. Collodion positives should always be taken in a non-reversing slide.

Positive pictures may be obtained from negatives in a variety of ways. *FRY*, after developing the image with the prosalts of iron above-described, changed the negative to a positive by pouring upon it a mixture of pyrogallie acid and hyposulphate of soda which had undergone partial decomposition, and warming gently. By this treatment the darkened parts are rendered brilliantly white from the formation of metallic silver. *ARCHER* pours a mixture of one part of a saturated solution of protochloride of mercury— Hg Cl —acidulated with hydrochloric acid and six parts of water upon one corner of the plate, and allows it to flow over the fixed negative picture. At first the shades are deepened, but quickly the appearance alters, and a very delicate white picture results. This picture may be alternately changed from positive to negative, and *vice versa*, by the agency of ammonia and the mercurial compound above applied alternately.

THE DRY COLLODION PROCESS.—In the former processes the excited collodion film is exposed and developed in its wet state, immediately after its removal from the nitrate-bath; but by attending to the following directions, it may be used dry, and kept for many months in a sensitive state. On removal from the nitrate-bath wash the film thoroughly in distilled water, so as to remove as much as possible of the free nitrate of silver from it. Then pour over it a tepid solution of gelatin, made by dissolving about six grains of gelatin to the ounce of distilled water, and adding about one drachm of alcohol, specific gravity .820. Set up the plate upon one corner against a wall to drain and dry in the dark. The exposure in the camera must be about six times longer than with wet collodion.

To develop the picture, first immerse it for a few minutes in a dish of distilled water, then pour over it the usual pyrogallie acid developer, to which a drop or two of a thirty-grain solution of nitrate of silver are added. The image comes out, and is developed as quickly as an ordinary wet collodion plate. It is then washed and finished in the usual way.

It is important to observe in this process that the measure in which the developer is mixed should be chemically clean; it ought, therefore, to be cleansed with cyanide of potassium, and well washed after every picture. In the ordinary wet process it is not absolutely necessary to take this precaution, although it is well to do so. The nitrate of silver added to the developer should be fresh solution, and not taken from the nitrate-bath.

The process just described was invented and patented by Dr. HILL NORRIS of Birmingham. It is extensively employed, and gives universal satisfaction. A very similar process has been introduced lately by Mr. FOTHERGILL; it consists in substituting albumen for gelatin, all the other operations remaining the same. When the plates are not required to be kept for more than a few days, this process succeeds pretty well; but for long keeping Dr. NORRIS's mode is the best. In FOTHERGILL's process the albumen is applied to the plate after washing off the nitrate of silver, and the plate is then washed again so as to remove the albumen. The pores of the collodion are probably filled with a compound of albumen and silver, which has been improperly termed *albuminate of silver*.

THE COLLODIO-ALBUMEN PROCESS.—This is a dry negative process which differs in an important particular from Dr. HILL NORRIS's or Mr. FOTHERGILL's. After the excited collodionized plate has been washed with water, iodized albumen is poured over it, and it is either allowed to dry, or dried before a fire. It is then insensitive to light. It is excited by immersing it in a bath of acetate of silver; after which it is washed and dried. The development is effected by immersing the plate in a solution of gallic acid, to which a few drops of acetate of silver are added. The negative is then fixed and finished in the usual way.

The iodized albumen is composed of about equal parts of albumen and water, to every ounce of which about six grains of iodide of potassium are added. This is then beaten up to a froth, and allowed to settle in the usual way. The bath of acetate of silver

contains fifty grains of nitrate of silver and one drachm of acetic acid to the ounce of water.

This process is more complicated and troublesome than any other, and the negatives are of a bad color, having a strong tinge of yellowish-green.

PRESERVATIVE PROCESSES.—In certain processes, instead of allowing the excited collodion film to get dry, a sirup is poured over it, which is completely washed off before the development. Golden sirup, honey, and oxymel have been employed. The former is probably the best, from its not containing either grape sugar—which is a reducing agent and causes partial decomposition and stains, when the plate is kept too long—or an acid, which renders the plate extremely insensitive, and destroys the half-tones. In using golden sirup, the nitrate of silver is first washed off and then the sirup applied; after exposure the plate is well washed to remove the sirup, and then developed as in Dr. NORRIS's process.

The objections to the moist preservative processes are, that wet sticky plates are liable to contract dust, and cannot be closely packed one upon the other for a journey as dry plates can. This mode of operating is, however, useful when the plate is prepared in the morning and developed in the evening of the same day.

To describe fully all the difficulties which beset the tyro in the manipulation of the various collodion processes, and to point out the causes of failure and the means of remedying them, would occupy too much space to be attempted in this work. In fact, each separate process, to be thoroughly explained and discussed, would occupy a volume. There is, however, a strong analogy between them all, and a theory which appears to include them all. This the Editor will now proceed to discuss.

THEORY OF THE COLLODION PROCESSES.—The sensitive collodion film is composed of iodide of silver, free nitrate of silver, and collodion. The iodide of silver is formed by immersing the iodized collodion film in the bath of nitrate of silver, so that iodide of potassium, plus nitrate of oxide of silver, becomes iodide of silver, plus nitrate of oxide of potassium—that is, nitrate of potassa. Now the collodion in the above combination appears to have a retarding effect on the action of light, because when a mixture of iodide of silver and nitrate of silver alone is exposed to light, it darkens more rapidly than when collodion is present. The collodion must not, therefore, be considered as an accelerator, but as the vehicle for supporting the sensitive chemicals upon the glass, and forming with the reduced silver an opaque compound in the darker parts of negatives. In the development of the picture, the pyrogallie acid accelerates the reduction of the silver salts on those parts on which the rays of sunlight have fallen, producing finely-divided metallic silver, which constitutes the blacks of the negative. The acetic acid, added to the pyrogallie developer, prevents its spontaneous or too rapid decomposition when mixed with the nitrate of silver. When, in the development of a positive, protosulphate of iron is used instead of pyrogallie acid, the difference between it and the organic acid mentioned is attributable to the fact, that it does not reduce as much of the metal as

the latter; consequently the precipitate is thin and transparent, and looks white when viewed by reflected light.

When cyanide of potassium is used to fix the picture, that is, to remove the iodide of silver, it has but little action on the image, while it decomposes the iodide of silver, and forms a soluble double cyanide of silver and potassium, together with iodide of potassium. When hyposulphite of soda is used, the iodide of silver is decomposed, and the products are a soluble double hyposulphite of silver and soda, together with iodide of sodium.

It appears that the maximum degree of sensitiveness in the film, is when it contains a certain excess of free nitrate of silver; so that, in the dry processes, the sensitiveness is reduced to a minimum by washing off the free nitrate; and in developing dry plates it is necessary to add nitrate of silver to the developer, to insure depth of shade by the deposition of more silver on the affected parts. It is necessary to wash off the free nitrate of silver from the plate for this reason, that if allowed to remain and get dry in the film it becomes concentrated by evaporation, and a concentrated solution of nitrate of silver has the property of dissolving iodide of silver, and rendering the film transparent and insensitive, by forming a salt called idonitrate of silver.

THE ALBUMEN NEGATIVE PROCESS UPON GLASS.
—As indicated in the brief historical notice to this article, albumen has long been employed upon glass as the basis of photographic pictures, so likewise has gelatin, and the results which both these yield are very satisfactory. The principal operations concerned in taking the picture with prepared albumen are, with few exceptions, the same as those practiced in working with collodion. The following description will indicate any slight differences in the manufacture.

To Prepare the Albumen.—Collect in a basin the whites of a number of eggs, carefully separating the germ, and all portions of yolk. To each ounce of this albumen add one drachm of distilled water, in which are dissolved six grains of iodide of potassium; also to every five ounces of the mixture add one drop of ammonia. Beat the whole to a stiff froth with a bunch of quills, and allow the liquid to settle till the following day.

To Albumenize the Plate.—The glass plate must first be cleaned very thoroughly, dried, and polished with a cambric handkerchief just before use. Attach to the under side of it a gutta-percha plateholder, having a wooden handle a foot long. Then breathe on the plate, and, holding it horizontally in the left hand, pour upon the centre of it a sufficient quantity of the albumen from the basin to cover it, allowing the albumen to filter through an opening in the dry froth or crust. Make the albumen flow backwards and forwards over the plate three or four times, and then allow the excess to run off into a separate basin, from which it must be carefully filtered before being used a second time. In coating the plate, be careful to remove with the point of a fine camel-hair pencil any air-bubbles which may have formed upon it. Next, take the handle of the holder between both hands, and, with the plate in a vertical position, spin it round quickly for a minute

or so, in order to drive the albumen to the edges by centrifugal force. This done, remove the excess of albumen from the edges by means of a pipette, and dry the plate before a clear fire, keeping it rotating all the time by means of the handle, as before directed. When dry it is ready for the next operation. Albumenized plates may be put away in a platebox, and kept in a dry place for a considerable time without deterioration. Care must be taken in the operation of albumenizing the plate that no particles of dust adhere to it.

Many practitioners find it more convenient to apply a dilute solution of albumen at first, and then by means of a pipette, in which as much of the prepared albumen has been taken up as will suffice for one plate, applying it in horizontal lines almost bordering upon one another. A gentle horizontal oscillating motion afterwards serves to spread it in an even layer, leaving an excess in no part. There are many other methods recommended in treatises and journals, but they need not be dwelt upon here; for every operator, knowing that the desideratum is to get a smooth homogenous layer of the albumen on the plate, will contrive in his own peculiar way to do so effectually.

To Excite the Plate.—Place it on a dipper, and immerse it quickly and without hesitation in a vertical bath of acetate of silver, made thus:—Distilled water one ounce, nitrate of silver fifty grains, glacial acetic acid one drachm. Leave it in the bath for a couple of minutes, then wash it well in clean water, and lastly in distilled water, and set it up to dry. When dry put it away in the platebox until ready for use in the camera. It may be preserved in a sensitive state for several days. Some persons add a few drops of a solution of iodide of potassium to a new nitrate-bath, and filter it on the following day, in order to saturate it with iodide of silver. When this is done a new bath is not so liable to attack the iodide of silver in the film.

The Exposure.—Albumenized plates, from which the excess of free nitrate of silver has been removed by washing, are, whether used in a dry or wet state, extremely sensitive to light; but, when only slightly washed, exposed at once, and developed with a strong developer, a much shorter exposure is sufficient. This should be timed solely with reference to the shadows, the lights being left to take care of themselves. When the camera is properly constructed, so as to prevent stray light from falling on the plate, it is hardly possible to over-expose a dry, washed, albumenized plate.

To Develop the Image.—Immerse the plate in distilled water; then place it on a levelling-stand, and pour over it a saturated solution of gallic acid, to which a few drops of acetate of silver have been added. The development occupies about twenty minutes.

To Fix the Picture.—Wash the plate in rain water, and pour over it a nearly-saturated solution of hyposulphite of soda. This will quickly remove the yellow iodide of silver from the film. Then wash the plate well under a tap, and dry it before the fire.

The negative may be varnished with any good varnish, but this is not always done.

A great many modifications have been adopted with albumen to give greater sensitiveness and quickness of

effect. Serum of milk, honey, and a dense solution of sugar have been mixed with the albumen, in order to get a coating of silver possessing more body than can be obtained by the albumen alone. HUNT introduced the use of fluoride of potassium mixed with iodide; and this method, in the hands of M. BLANQUART EVERARD, is said to be so sensitive as to give pictures on instantaneous exposure.

THE CALOTYPE OR PAPER PROCESSES.—These processes are founded on the same principle as the collodion and albumen methods, the only difference being that the vehicle for supporting the chemicals is paper instead of a collodionized or albumenized plate. They may be divided into two classes according to the mode of operation pursued, and the chief difference between them consists in the mode of rendering the paper sensitive, that is, in the order in which the ingredients are introduced, the mode of development being nearly the same in all, and merely involving a difference in the strength of the developer and the mode of applying it.

Considerable attention must be paid to the quality of the paper, for every kind is far from being applicable. That most suitable is a white paper as pure as possible from mineral matters, having a close fibre, sized either with starch or gum, and well pressed, to render the surface fine and even and homogeneous throughout. Unsized paper does not give satisfaction when silver salts are the sensitive agents, as it absorbs too much of the materials, and the picture is developed rather in the body of the material than upon its surface. These requirements are happily understood to a great degree, and manufacturers devote attention to the production of a paper possessing many of the qualities which the photographer requires.

The calotype processes may be classed under two heads. In the first the paper is coated with insensitive iodide of silver, and then excited by a weak solution of acidified gallonitrate of silver; in the second class, the paper is first coated with an alkaline iodide, and then excited by immersion in a *strong* bath of nitrate of silver, the excess of free nitrate being subsequently removed by washing. Of these, one will be selected for minute description, which appears to be, of all the calotype processes, the simplest in manipulation and most scientific in principle. In the processes of Class I. the paper is iodized with iodide of silver; in those of Class II. with a soluble alkaline iodide. The first kind of iodized paper may, for convenience, be called *argento-iodized* paper, the second kind simply *iodized* paper.

Chloride of Silver Paper.—For a variety of purposes, more especially for copying from negative pictures, papers on which a surface of chloride of silver has been produced is extensively used. The manipulations by which the above is effected consist in first saturating wholly or in part with chloride of sodium solutions, and subsequently with those of nitrate of silver; chloride of silver is formed by a well-known process of double decomposition, thus—

The strength of the solutions employed are various, dependant always upon the amount of sensitiveness required. In practice the quantity of materials per

ounce of distilled or rain water indicated below are the most general:—

	Grains. I.	Grains. II.	Grains. III.
Chloride of sodium,.....	30	25	20
Nitrate of silver,.....	120	100	60

These solutions are applied in even strata to the paper, preference being given by some persons to the alkaline salt, by others to the silver compound; and it would appear that the latter practice is more commendable, as it insures a surface better coated with the silver than if it were applied after the soda salt. The manner of coating these papers being the same as when preparing them with iodine compounds for taking impressions in the camera, and which is to be detailed, will not be dwelt upon. It may be remarked, however, that when they are to be used, the sensitive side should be recently washed with a dilute solution of nitrate of silver, as it adds considerably to the effect of the light upon them.

Iodide of Silver Paper.—It may be premised here that, however varied the methods of manipulation of different photographers may be, if they be not calculated, firstly, to secure a uniform coating of iodide of silver over every part of the surface of the paper; and, secondly, an even distribution of a small quantity of nitrate of silver, or, where great sensitiveness is required, of this salt mixed with a reducing agent—gallic acid—and an entire absence of alkaline salts before the paper is placed in the camera, they should not, as the science and practice of photography is at present understood, be adopted. Without these conditions being supplied good pictures cannot be obtained by this method.

CALOTYPE PROCESSES—CLASS I.—There are *two* methods which come under this head. In the first, argento-iodized paper is prepared by what is called the *double wash*; in the second, by the *single wash*. In all other respects the two methods are identical.

To Argento-iodize the Paper by the Double Wash.—Float the face of the paper on a bath containing twenty grains of nitrate of silver to the ounce of distilled water. Let it remain a minute or two in the bath, then hang it up to dry. Next immerse it in a solution containing twenty-five grains of iodide of potassium to the ounce of distilled water. Let it remain a minute or two in this solution, the exact time depending on the kind of paper employed, and requiring to be ascertained by experiment. If too short a time is allowed, the whole of the nitrate of silver is not decomposed, and the paper darkens in the light; if, on the contrary, too long a time is allowed, the iodide of potassium in the bath dissolves the iodide of silver in the paper. The time of immersion in the iodide-bath is therefore rather critical. On removing the paper from the bath, let it drain, and then immerse it in a pan of water, in which it must be allowed to soak, the water being changed several times, until the *whole* of the free iodide of potassium is removed. This soaking operation is rather troublesome, and the texture of the paper is decidedly injured by it. Should any excess of iodide of potassium remain in any part of the paper, it would decompose the weak exciting solution and produce insensitive iodide of silver, and consequently a white patch in the negative. When the paper has been sufficiently washed, hang it

up to dry. It is of a yellow primrose color. When dry, it may be kept for use in a portfolio. It is not sensitive to light.

To Argento-iodize the Paper by the Single Wash.—Lay the paper on a board with a piece of blotting paper under it, and brush over it a solution called *double iodide*; that is, a solution of iodide of silver in iodide of potassium. The best kind of brush is a large round one of camel's hair, bound with string or silver wire. Apply the solution copiously both longitudinally and transversely, inclining the board, and keeping a flowing edge. Hang up the paper to dry in a room having a pure atmosphere, free from sulphurous or other acid vapors. When very nearly or even quite dry, immerse the paper in a pan of water as before, to remove completely the excess of iodide of potassium which it contains. Two or more papers should not be soaked in the same pan, but each paper ought to have a separate one. When sufficiently washed—an operation which requires several hours—dry, and keep it for use.

The solution called *double iodide* is made by dissolving twenty grains of nitrate of silver in one ounce of distilled water, and adding crystals of iodide of potassium, a few at a time, until the yellow turbidity at first produced in the solution is quite cleared up. The quantity required is nearly half an ounce. The menstruum should be filtered before use.

Argento-iodized paper will retain its good qualities for some weeks. Some persons even affirm that it may be kept for an indefinite period in a dry place. It is said, on good authority, to be much improved by exposing it for an hour or two to strong sunshine. When this is done, it should not be excited immediately after insulation, but kept for some days previously in the dark, since it has been found that paper absorbs light in sufficient quantity to react on a sensitive surface placed in contact with it in the dark.

In comparing the two foregoing methods of iodizing the paper, it will be seen that the first is the most economical, but at the same time the least certain. A considerable quantity of iodide of potassium is wasted in the second mode of iodizing, and the washing operation is rather more tedious.

The paper having been iodized by either of these methods, may be proceeded with as follows:—

To Excite the Paper.—Make a saturated solution of gallic acid in cold distilled water, which call solution A; and another, by dissolving fifty grains of nitrate of silver in one ounce of distilled water, and adding one drachm of glacial acetic acid, which call solution B. Immediately before use, mix, in a chemically clean measure, one ounce of distilled water, fifteen drops of solution B, and about as many drops of solution A, the number of the latter depending on the temperature and kind of paper employed.

Lay the paper on a board with a piece of blotting paper beneath, and apply this mixture copiously to it with a clean Buckle's brush. Hold up the paper to drain for a minute, then abstract the surface moisture with clean blotting paper, and place it in the dark slide.

The Exposure.—The average time of exposure, with

a good light, a lens of fifteen inches focus, and a half-inch stop, is seven minutes.

To Develop the Picture.—Lay it on a board, and brush over it with a clean Buckle's brush, a mixture composed of three parts of solution A, and two parts of solution B. The picture, the darker parts of which are at first faintly visible, soon comes out of a fiery red tint. At this stage of the development it is necessary to check it, in order to obtain dense blacks instead of feeble reds in the darker parts of the negative. To accomplish this, brush over the picture, and complete the development with a solution of gallic acid alone.

Under this treatment the reds soon darken and intensify, and become eventually opaque blacks. The active development should occupy about twenty minutes. It is an excellent plan, after having brushed on the gallic acid, to lay the paper face downwards on a horizontal glass slab, on which a quantity of gallic acid solution has been previously spread.

To Fix the Picture.—When the details are fully out, and the blacks of the proper intensity, wash the negative with water, and then immerse it in a solution containing one part of hyposulphite of soda to four of water. Let it remain until the whole of the yellow iodide of silver dissolves; then wash and soak in water for several hours, changing the water several times, in order to remove the whole of the hyposulphite from the paper, and hang it up to dry.

The negative is now finished, and may be waxed at any convenient time in order to render it more transparent. This is done by melting some white wax in a vessel placed in a shallow pan of boiling water, applying it with a clean hogs'-hair paint-brush to the picture, which should be placed between sheets of blotting paper, and a moderately-hot iron passed over the whole until no shining patches of wax are seen.

There are one or two important points to be observed in this process. If the iodized paper is excited with a weak solution of aceto-nitrate of silver containing no admixture of gallic acid, it is quite as sensitive, or even more sensitive than before, but the negative is devoid of density, and the dark portions are grey, feeble, and metallic, like the dark parts of a collodion positive on glass when viewed by transmitted light. This shows that it is necessary to employ a substance—gallic acid—that will continue, as it were, the chemical effect of the radiant agent, or the proper tones cannot be produced. If, on the other hand, too much gallic acid is added to this solution, the reducing effect will be so great that the paper is liable to become brown all over, particularly in hot weather. The process has, therefore, its drawbacks and uncertainties, particularly in that season of the year when photographic tourists are most in want of a good process. A good test of the proper state of the sensitive paper is to take a strip into the light. If it darkens instantly to a cold grey tint, incapable of being intensified by the further action of light, the negatives will probably be grey and feeble; but if it assumes a redder tint, which becomes still darker by continuing the exposure, there is sufficient matter present to give a good intense picture.

CALOTYPE PROCESSES—CLASS II.—In these processes the operations consist in first impregnating the

paper with an alkaline iodide; next, rendering it sensitive by immersion in a strong bath of aceto-nitrate of silver; and developing with gallionitrate of silver rather weaker than that used in the foregoing process.

To Iodize the Paper.—Immerse a number of sheets, one at a time, in a solution of iodide of potassium containing twenty grains of the salt to the ounce of distilled water. Let them remain together in the bath for at least a couple of hours, then hang up to dry, after which they may be kept in a portfolio for use.

To Excite the Paper.—Immerse it in a bath of acetonitrate of silver, containing thirty-five grains of nitrate of silver, and two scruples of glacial acetic acid to the ounce of water. First, float the face of the paper for a few seconds on the bath, then immerse it entirely for nearly three minutes, and then remove it into a dish of distilled water. Rinse well, then press it between blotting paper and put it into the slide, with its face to the front shutter.

The Exposure.—This is about the same as in the former process.

The Development.—The paper will scarcely exhibit any trace of an image. Immerse it in a solution of gallic acid, to which a few drops of aceto-nitrate have been added. The picture should not exhibit itself of a grey tint but red, which should darken in the course of the development to an intense black in the deepest parts. The dish should be chemically clean, and the developer should remain colorless throughout; the whites of the picture will not then be discolored, and the development will proceed much more quickly.

If the picture comes out grey and metallic, exhibiting all the detail, and having but little intensity, it indicates a want of a reducing agent in the sensitive film. To remedy this, add a little citrate of soda to the iodizing solution. This will entirely alter the character of the picture, increasing the density of the black, and also the necessary time of exposure. Sugar, honey, gelatin, and substances of this kind added in large quantity to the iodizing solution produce little or no effect. Serum of milk contains some organic salts—lactates—which are decomposed and form corresponding salts of silver.

As a rule, it may be considered that organic salts, which at once decompose nitrate of silver and form an insoluble organic compound with oxide of silver, act most powerfully in producing blacks; for instance, as gallic acid, which when added to nitrate of silver, forms a mixture which is immediately decomposed by light, metallic silver being produced. It is a convenient plan, when travelling, to develop without a dish, by turning up the edges of the picture and making it into a tray, into which the developer may be poured and spread with a glass rod.

To Fix the Picture.—Proceed as described in the former process.

Having described the simplest form of the second class of processes, it remains to indicate the various modifications which it has assumed. The first and most important of these consists in waxing the paper before iodizing it. This modification has received the name of the *Waxed-paper Process*.

Wax being nearly inert as regards its power of com-

bining with silver and forming an organic compound of that metal, its presence does not modify the character of the negative in any appreciable way as regards density; nor does it appear that any other good is derived from the introduction of wax in the first stage of the process, than stiffening the paper, and rendering it less liable to be torn in the various operations. The wax and fatty impurities contained in all the commercial samples cause it to repel water, so that there is some difficulty in getting a sheet of waxed paper to imbibe the solutions. This may be overcome by dissolving a few shreds of gelatin in the iodizing solution, and by adding a little alcohol to the gallic acid. In all other respects the waxed-paper process is the same as that previously described.

The other processes of Class II. are merely modifications of the waxed-paper process in its simplest and best form, as described above. They consist in adding various organic substances, such as rice-water, gelatin, honey, and the like, and also bromides, cyanides, fluorides, *et cetera*, to the iodizing solution. Most of these organic substances are nearly, if not absolutely inert, and many of the salts added are of very questionable utility. It would appear, however, that the bromide of potassium may be employed to replace the iodide of this base with a good effect, especially in taking landscape views, since it gives a better result as to light and shade. A word or two may be said on the subject of substituting iodide of cadmium for iodide of potassium in the paper processes. It is a tolerably good salt to employ when pure, and the negative is free from the white spots which sometimes occur when a crystal of iodide of potassium remains undecomposed. But the nitrate of cadmium introduced into the nitrate-bath has an acid reaction which resembles, in a slight degree, the reaction of the nitric acid. This renders the paper less sensitive, increases the difficulties of bringing out the details of the shadows, and diminishes the density of the blacks.

Before concluding an article which embraces a description of the most important modes at present known, of obtaining negatives on paper, it may be well to discuss the points in which these processes are inferior to the analogous ones on glass.

The principal fault of a calotype negative consists in the fact, that a sheet of paper, waxed in the ordinary way, is not evenly transparent when held against the light, but exhibits a granular appearance, and sometimes the marks of the wire frame used in its manufacture. Before a paper negative can be expected to rival one on glass, this radical defect must be overcome. Now, it will be found that if a sheet of paper is dipped for a minute or two in linseed oil and dried, it will exhibit precisely the same defects as one that is waxed; but if left in the oil for a week, so as to imbibe it thoroughly, it will appear as evenly transparent as could possibly be desired. It is obvious, therefore, that the radical fault of a calotype negative consists in the paper not thoroughly imbibing the wax, which would evidently be a work, not of minutes but of hours, or even days. Fortunately, however, the inconvenience may be repaired by a very simple process. If one half of a sheet of paper be immersed in a mixture con-

taining equal parts of hydrochloric acid and water, thoroughly rinsed in several changes of water, and dried, it will be found, in waxing the whole sheet, that the half which has been treated in the manner described imbibes the wax much more readily than the other half, and presents a beautifully even appearance.

A finished negative on plain paper may be treated with hydrochloric acid with perfect safety, since it does not attack the image, unless very strong.

Another frequent defect of paper negatives is a want of half tone, too great intensity in the blacks, and too little detail in the shadows. In such cases the fault may generally be corrected by lessening the quantity of the organic reducing agent, by diminishing the acidity of the nitrate-bath, and increasing the time of exposure.

Lastly, the paper processes are very insensitive when compared with wet collodion. This may proceed from the great quantity of acid used in the acetone-nitrate-bath in paper work, as compared with the neutral, or, at least, but slightly acid one, in collodion work.

The best paper to employ in these processes is HOLLINGWORTH'S *thin* photographic paper; WHATMAN'S is also recommended.

THE PRINTING PROCESSES.—There are several methods of printing positives from a negative. Some of these consist in producing prints upon paper, others in producing prints upon glass, which are intended to be viewed as transparencies. The negative processes are always employed for the latter, and the negative is either copied by superposition upon a dry albumenized or collodionized plate, or by means of a lens upon a wet one. In the former case, an exposure of a second or two to diffused light is sufficient. In the latter, a portrait lens is employed, with a stop between the lenses, and the time of exposure depends on the size of the stop. The negative should be so placed as that the light from the northern sky is transmitted through it. Stereoscopic transparent prints are very beautiful when properly executed.

There are many ways of printing upon paper. They may be classified as *carbon printing*, *uranium printing*, *ink printing*, and *silver printing*. These various processes differ in principle, and must be treated separately.

Carbon Printing.—This process is the most economical, simple, and permanent of any. As first practised and published by Mr. POUNCY of Dorchester, it consists in blackening a sheet of paper all over with a mixture of vegetal carbon, gum arabic, and bichromate of potassa, drying it, and exposing it to light under a negative. Where the light acts the bichromate is reduced, and the black mixture rendered insoluble. The paper is then immersed for some hours in water, which entirely removes the unaltered carbon mixture from the paper, leaving the lights tolerably pure. The print is then finished.

Simple as this process may appear, it was found to succeed only in the hands of the inventor, who disposed of it for a sum of money, reserving to himself the sale and secret of a peculiar paper which he professed to be essential to its success. Even in Mr. POUNCY'S prints the lights were by no means quite pure, and the blacks were disfigured by a yellowish or greenish tinge; while many experienced photographers who had sub-

scribed to raise the amount demanded for the publication of the secret, complained that, after following most carefully the inventor's published directions and using his own paper, their efforts had resulted only in repeated failures. While this article is going through the press, however, the Editor learns that the difficulties and uncertainty attending the process have been overcome by an amateur photographer, Mr. W. BLAIR of Perth, who observed that the greater part of the black compound lay on the surface of the paper, without penetrating it, thereby preventing the light which passed through the negative from reaching the paper; and what did reach the paper acted with greater or less effect at different points, according to the varying thickness of the carbon coating, which it is impossible to spread with the brush with absolute regularity. On thinking over this matter it occurred to him, that to get a good picture with anything like certainty and ease, the process must in some way be reversed, and that the carbon must be *lighted* or *sunned* from the other side, that is, on the side *next the paper*; and that the only way to do this was to use thin paper, and turn the back or white side of it to the negative. Having found by experiment, also, that something must be laid on the paper besides the very soluble gum, to prevent the carbon from being removed in the final washing, and conceiving that albumen possessed the desired property, he tried the *reversed* method with MARION'S albumenized thin paper, and found it to succeed perfectly, yielding, with full sunshine and an exposure of one or two hours, prints which are pronounced by a high photographic authority to be remarkable for the vigor of the blacks and the purity of the whites. The blacks, says Mr. SUTTON, precisely resemble those of an engraving, being entirely devoid of gloss, free from the greenish yellow tinge observable in Mr. POUNCY'S prints, and reminding one of black cloth. If the process, on further trial, shall continue to deserve these commendations, it will be creditable to Mr. BLAIR, that, unlike many photographers, he has given his secret to the world gratuitously: for carbon printing, on account of the absolute permanence which it ensures—a quality which has long been the great desideratum in photography—must ultimately, if carried to high perfection, supersede all other processes.

Uranium Printing.—In this process a sheet of paper is immersed in a saturated solution of nitrate of uranium, and dried in the dark. It is then exposed under a negative to sunshine for a few minutes. Where the light acts, the uranic salt is reduced, and a faint positive picture obtained. This is intensified to a deep purple tint by immersing the paper in a solution of chloride of gold; strength, half a grain to the ounce of distilled water. After which it is well washed in water, dried, and the print is finished.

Ink Printing.—By means of this process, positive prints may be obtained in common writing ink. A sheet of paper is immersed in a nearly saturated solution of bichromate of potassa, and dried. It is then exposed under a negative to sunshine for a few minutes. Where the light acts the bichromate is reduced, and a brown positive upon a yellow ground obtained. This is well

washed in many changes of water, and the yellow bichromate thereby removed. The print is now fixed, and is of a pale brown tint upon a white ground. It is intensified by being immersed for a few minutes in a solution of protosulphate of iron, five grains to the ounce; then washed in several changes of water; and, lastly, immersed in a moderately strong solution of tannic acid. The ferruginous salt, which adheres only to the image, is thereby converted into tannate of iron, or common writing ink.

The Silver Printing Processes.—There are two different methods of printing with the salts of silver—one called sun printing, in which the print is produced in its full intensity by exposing a sensitive paper to light under a negative; the other, called development printing, in which a faint image, obtained by the direct action of light, is intensified by a process of development.

In sun printing, the paper may be either plain or albumenized; but as the methods of toning the print are different in the two cases, they must be described separately.

Sun Printing upon Plain Paper.—Dissolve, with the aid of heat, four grains of gelatin and four grains of common salt to the ounce of filtered rain water. When cold strain it through a fine muslin into a shallow dish larger than the sheet of paper to be printed upon. Use the best Saxe paper, and float the face of it for a couple of minutes upon the above solution. Hang it up by one corner to dry. When dry lay it upon a board, and brush over it a solution of ammonio-nitrate of silver, made thus:—Dissolve fifty grains of nitrate of silver to the ounce of distilled water, and add liquor ammoniæ to the solution, drop by drop, until the brown turbidity, which is at first formed, is entirely redissolved, and the liquid rendered again clear and colorless. This turbidity is due to oxide of silver which is at first thrown down, and then redissolved by the addition of more ammonia. The best kind of brush to employ is what is called a Buckle's brush, made by pushing a tuft of cotton wool into the open end of a glass tube. The paper should be brushed, first longitudinally, then transversely, and after being left to imbibe for two or three minutes, it should be brushed again, then hung up to dry. As soon as it is dry—for it would turn brown by keeping—it should be exposed to light under the negative until it is rather deeply printed, then taken from the pressure frame, well washed in rain water, then in water to which a few drops of ammonia are added, afterwards in water again. The picture is now a deep slate color, and still sensitive to light.

The next process is to tone it, that is, to substitute gold or oxide of gold, for the silver, which forms the shadows of the picture. This is done by immersing the print for two or three minutes in the following solution:—

Distilled water,	2 ounces.
Hyposulphite of gold and soda,	1 grain.
Pure hydrochloric acid,	5 minims.

In this bath the tint of the shadows changes to a deep purple, and the lights sometimes become slightly yellower. While in the toning-bath the changes of color may be watched by feeble diffused daylight. The

print must then be washed in several changes of water, until all traces of acidity are removed, and fixed by immersion in a solution of one part of hyposulphite of soda to twenty parts of water. In this it should remain about twenty minutes, and the solution should then be thrown away, and the print well washed and soaked in water, many times changed during some hours, after which it is dried. The print is then finished.

Sun Printing upon Albumenized Paper.—A mixture of equal parts of albumen and water, to every fluid ounce of which six grains of salt are added, must be beaten up to a froth, and allowed to settle. Filter the clear liquid through two layers of damped muslin into a shallow dish, and float the sheet of paper—CANSON'S or MARION'S—upon it for a minute, then hang it up to dry. When exsiccated excite it by floating it upon a solution of nitrate of silver, containing forty grains to the ounce of distilled water. Hang it up to dry. The paper should be exposed under the negative until the print is darker than it is intended to be ultimately. On removal from the pressure frame put the print into the following solution:—One part hyposulphite of soda to six parts of water, to every ounce of which half a grain of chloride of gold is added. Leave it in the solution until the red tint which it at first assumes has deepened considerably. Then remove it, wash it in several changes of water, and let it soak for several hours; desiccate it, and it is finished.

Printing by Development.—HOLLINGWORTH'S thin paper is to be preferred to any other. Immerse it in a solution containing six grains of salt and one part of iodide of potassium to the ounce of rain water. When dry, brush over it, precisely as in the ammonio-nitrate process, the following solution of nitrate of silver:—

Distilled water,	1 ounce.
Nitrate of silver,	30 grains.
Lemon juice,	6 drops.

Expose in the pressure frame until a faint image is produced; this will require a few seconds only. Then turn up the edges of the paper so as to form the print into a tray; place it upon a perfectly horizontal sheet of glass, and pour into it a small quantity of a saturated solution of gallic acid, which spread quickly over all parts of the print with a bent glass rod. The image immediately begins to intensify. At first it comes out of a fiery red tint, which ultimately passes to a black. As soon as it is sufficiently developed, wash it in two or three changes of water, and fix it by the same treatment as that described in the ammonio-nitrate process; but gold toning is unnecessary. Prints produced by this, or by the ammonio-nitrate process with gold toning, are permanent. Those printed by the albumenized paper process frequently fade.

Before closing this part of the subject, it may be mentioned that the light of the sun is not directly essential to the production of pictures, the light of the moon and stars being sufficient to give an impression of those bodies—a fact highly interesting to astronomers. Considerable condensation of the light is required, and also a lengthened exposure. With the exception of the mechanical adaptations for throwing the light on the sensitive plate, and retaining the image on the same

part during the necessary time, the operations are the same as in ordinary photographic practice. A

Fig. 413.

method has recently been invented by Mr. JOHN MOULE of London for taking positive photographs by means of artificial light, and which is reported to be quite satisfactory. The author has given the method the title Photogenic, and the apparatus suited for the purpose he calls the *Photogen*. The latter is a kind of lamp, hexagonal in form, and supported upon a stand of suitable height. The base, frame, dome, and chimney are of galvanized iron, and the sides of glass. In the bottom, as shown in the sketch—Fig. 413—are a number of holes to admit air, and a pan is fixed in the centre, wherein the combustibles for yielding the artificial light are consumed. The composition which the inventor uses is—

Pure saltpetre—nitrate of potassa,.....	112 parts.
Flowers of sulphur,	42 "
Black antimony—sulphide,.....	12 "

It is said that the light emitted by the combustion of this matter is highly charged with the actinic rays that effect the decomposition of the photographic agents, and that the portraits which are taken by it leave nothing to be desired. A square of blue glass introduced between the light and the sitter protects the latter from the glare, at the same time that it does not weaken the effect in the camera. All the other operations are the same as when taking portraits in the sunlight. It is needless to say that the invention, when it becomes more known, will be a great acquisition to photographers and amateurs generally, as it will place them beyond dependence upon the changes of the weather in times and seasons.

PHOTO-LITHOGRAPHY.—This is a process of obtaining a lithograph upon stone by means of photography, from which copies may be printed in printers' ink in the usual way. The best method appears to be that which was recently patented in England by Messrs. CUTTING and BRADFORD of Boston, U.S.

They spread a composition of water, one quart; gum arabic, four ounces; sugar, one hundred and sixty grains, and bichromate of potassa, one hundred and sixty grains upon the stone, which must be preserved in the dark until required, and when the coating is dried it may be exposed in the camera a suitable length of time, or it may be covered by the print or picture to be reproduced and exposed to the light. After it is thus *lighted* it is washed with a solution of soap, which removes the coating from

every part, except where the light has operated in rendering the gum and chromium compound insoluble in the menstruum.

It would appear, by the terms of the specification, that an insoluble soap is supposed to be deposited, or produced, on the surface of the stone, but the explanation given by the patentees is very dubious.

The most delicate grades and tints of light and shade may thus be produced upon the stone, true to nature as the photographic picture itself. The stone having been thoroughly washed with clean water and dried, now receives a coating of ink from the roller, which, uniting with the soap already deposited thereon, serves to give additional body to the picture, and shortly after the stone is ready for the printer; the portions which have been protected by the undissolved or *lighted* gum when wet resisting the ink.

Previous to the commencement of the above-described process the stone is to be prepared, and this preparation will vary according to the nature of the picture or subject to be produced. If it be a manuscript, a lithograph, line engraving, or any plan or line drawing without gradations of light or shadow, running the one into the other, a polished surface may be employed. This will not answer, however, so well for portraits, landscapes, and a great variety of other pictures in which the variations of shade blend the one into the other: in such cases it becomes necessary to give the stone a roughened surface, or, in the language of the workman, the stone is *grained*. Into such a surface the chromated solution of gum sinks deeper, and is then removed more or less according as it has been fixed by the light, and thus the required variations of intensity and the gradations of light and shadow are produced. Where a polished stone is employed, the chromated gum lies upon the surface, and it is found that the variations of light and shadow cannot be produced with that nicety necessary to make a perfect graduated picture such as a portrait that shall be easily printed.

The claim of the patentee is simply confined to the use of gum-arabic mixed with sugar, and of soap for removing the unchanged coating, and depositing an insoluble saponaceous film on the stone, that enables the latter to combine with the ink. All the other ingredients may be modified as to quantity at pleasure.

PHOTOGLYPHIC ENGRAVING.—The process thus designated was patented by Mr. FOX TALBOT in April, 1858; it consists in etching, by purely chemical means, a positive photograph printed upon a copper plate.

Plates of steel, copper, or zinc, such as are commonly used by engravers, are employed. Before using a plate its surface should be well cleaned. It should then be rubbed with a linen cloth dipped in a mixture of caustic soda and whiting, in order to remove any remaining trace of greasiness. The plate is then to be rubbed dry with another linen cloth. This process is then to be repeated, after which the plate is in general sufficiently clean.

The sensitive coating for receiving the image, is prepared by adding to about a quarter of an ounce of gelatin, dissolved in eight or ten ounces of water, by the aid of heat, one ounce, by measure, of a saturated solution of bichromate of potassa in water, and straining

the mixture through a linen cloth. The best sort of gelatin for the purpose is that used by cooks and confectioners, and commonly sold under this name. In default of this, isinglass may be used, but it does not answer so well. Some specimens of isinglass have an acidity which slightly corrodes and injures the metal plates. If this accident occurs, ammonia should be added to the mixture, which will be found to correct it. This mixture of gelatin and bichromate of potassa keeps good for several months, owing to the antiseptic and preserving power of the bichromate. It remains liquid and ready for use at any time during the summer months, but in cold weather it becomes a jelly, and has to be warmed before employing it. It should be kept in a cupboard or dark place. The proportions given above are convenient, but they may be considerably varied without injuring the result. The engraving process should be carried on in a partially darkened room, and is performed as follows:—

A little of the prepared gelatin is poured on the plate to be engraved, which is then held vertically, and the superfluous liquid allowed to drain off at one of the corners. It is then held in a horizontal position over a spirit lamp, which soon dries the gelatin, and the latter is left as a thin film of a pale yellow color, covering the metallic surface, and generally bordered with several narrow bands of prismatic colors. These tints are of use to the operator, by enabling him to judge of the thinness of the film. When it is very thin, the prismatic colors are seen over the whole surface of the plate. Such plates often make excellent engravings; nevertheless, it is perhaps safer to use gelatin films which are a little thicker. Experience alone can guide the operator to the best result. The object to be engraved is then laid on the metal plate, and screwed down upon it in a photographic copying frame. Such objects may be either material substances, as lace, the leaves of plants, *et cetera*, or they may be engravings, writings, photographs, or the like.

The plate bearing the object upon it is then to be placed in the sunshine, for a space of time varying from one to several minutes, according to circumstances; or else it may be placed in common daylight, but of course for a longer time. As in other photographic processes, the judgment of the operator is here called into play, and his experience guides him as to the proper time of exposure. When the frame is withdrawn from the light, and the object removed from the plate, a faint image is seen upon it, the yellow color of the gelatin having turned brown wherever the light has acted. The process, thus far, is similar to one which was patented by TALBOT in 1852. The novelty of the invention consists in the improved method by which the photographic image, obtained in the manner above described, is engraved upon the metal plate. The first improvement dispenses with the operation of washing the plate bearing the copied image in water, or a weak alcoholic solution, in order to dissolve the gelatin from the parts on which the light had not fallen, as recommended in TALBOT's patent of 1852. Instead of this, he immediately spreads over the surface of the plate bearing the picture, carefully and very evenly, a

little finely-powdered gum copal—in default of which common resin may be employed. It is much easier to spread this resinous powder evenly upon the surface of the gelatin, than it is to do so upon the naked surface of a metal plate. The chief error the operator has to guard against, is that of putting on too much of the powder; the best results are obtained by using a very thin layer of it, provided it is uniformly distributed. If too much of the powder is laid on it impedes the action of the etching liquid. When the plate has been thus very thinly powdered with copal, it is held horizontally over a spirit-lamp, in order to melt the gum. This requires a considerable heat. It might be supposed that this heating of the plate after the formation of a delicate photographic image upon it, would disturb and injure the image, but it has no such effect. The melting of the copal is known by its change of color. The plate should then be withdrawn from the lamp and suffered to cool. This process he calls the laying an aquatint ground upon the gelatin, and which he considers a new process. In the common mode of laying an aquatint ground, the resinous particles are laid upon the naked surface of the metal before the engraving is commenced. The gelatin being thus covered with a layer of copal, disseminated uniformly and in minute particles, the etching liquid—sesquichloride of iron—is to be poured on. It is prepared by dissolving sesquioxide of iron, with the aid of heat, in hydrochloric acid. After straining the solution to remove impurities, it is evaporated till it is considerably reduced in volume, and is then poured off into bottles of a convenient capacity. As it cools, it solidifies into a brown semi-crystalline mass. The bottles are then well corked up and kept for use.

This substance, when laid upon a metallic surface of iron, copper, or zinc, attacks these bodies by virtue of its excess of acid, being itself reduced to the state of a protosalt of iron, or if the action be continued with exposure to air, to sesquioxide, thus:—

Hence its use in the present invention.

A bottle—number one—is filled with a saturated solution of sesquichloride of iron in water. A bottle—number two—with a mixture consisting of five or six parts of the saturated solution, and one part of water; and a bottle—number three—with a weaker liquid, consisting of equal parts of water and of the saturated solution. Before employing these solutions to etch the photolyphic plate, TALBOT directs that it is necessary to make trial tests of their power, by applying a portion of number two bottle to metallic surfaces prepared as directed, observing, that when the etching goes on too rapidly, a quantity of the saturated liquid in number one bottle should be added to it. On the contrary, if the etching does not commence for a few minutes, or proceeds only slowly, it is a sign that the liquid is too dense, and requires dilution either with water or the contents of the third bottle; either of which ought, however, to be added very sparingly, as a small proportion of either gives great activity to the etching liquid. After the strength and power of the solution have been

determined by three or four such trials, it may be poured on the prepared plate, and spread evenly with a camel-hair brush. The liquid penetrates the gelatin wherever the light has not acted on it, but it refuses to penetrate those parts upon which the light has sufficiently acted. In this way the etching proceeds till all the details of the picture have become visible, and present a satisfactory appearance to the eye, which generally occurs in two or three minutes, the operator stirring the liquid all the time with a camel-hair brush, and thus slightly rubbing the surface of the gelatin, which has a good effect. When it seems likely that the etching will improve no further, it must be stopped. This is done by wiping off the liquid with cotton wool, and then rapidly pouring a stream of cold water over the plate, which carries off all the remainder of it. The plate is then wiped with a clean linen cloth, and rubbed with soft whiting and water to remove the gelatin. The etching is then found to be completed.

Another etching process, very slightly differing from the former, is also recommended. When the plate is ready for etching, pour upon it a small quantity of the liquid number one—saturated solution. This should be allowed to rest upon the plate one or two minutes. It has no very apparent effect, but it acts usefully in hardening the gelatin. It is then poured off from the plate, and a sufficient quantity of solution, number two, is poured on. This effects the etching in the manner before described, and if this appears to be quite satisfactory, nothing further is required to be done. But it often happens that certain faint portions of the engraving, such as distant mountains or buildings in a landscape, refuse to appear, and as the engraving would be imperfect without them, the operator is in that case to take some of the weak liquid, number three, in a small saucer, and without pouring off the liquid, number two, which is etching the picture, to touch with a camel-hair brush, dipped in liquid, number three, those points of the picture where he wishes for an increased effect. This simple process often causes the wished-for details to appear, and that sometimes with great rapidity, so that caution is required in the operator in using this weak solution, especially lest the etching liquid should penetrate to the parts which ought to remain white. But in skilful hands its employment cannot fail to be advantageous, for it brings out soft and faint shadings, which improve the engraving, and which would otherwise probably be lost. Experience is requisite in this as in most other delicate operations connected with photography. The claims of this invention are the etching of the plate without disturbing the coating of gelatin and bichromate of potassa, by washing; the laying of an aquatint of resin or copal upon the surface of the gelatin, after the production of the image, and the application of heat to melt it, and the use and employment of sesquichloride of iron as an etching liquid instead of nitric acid, for the production of photoglyphic engravings.

PHOTOGALVANOGRAPHY.—This process, to which allusion has been made in the historical notice, page 692, consists in obtaining from a photograph, and by means of electro-plating, a metal plate in raised and

sunk parts, from which impressions can be printed in printers' ink.

The positive print—generally on paper—is laid face upwards, on a sheet of glass coated with gelatin, containing bichromate of potassa, and dried; it is then exposed to light in a pressure frame for a few hours. The time of exposure, of course, depends on the intensity of the light. Sunshine is preferred, but is not necessary. The picture on the gelatin is developed in raised and sunk parts by immersion in water. Where the light has *not* acted, the gelatin swells and forms a ridge, or a series of minute granulations, but where it *has* acted, the gelatin is hardened and does not swell. The picture thus formed is very curious, and resembles a positive by reflected light, the shadows and dark parts being rough, and the lights smooth and polished.

A mould of the picture is then taken in gutta-percha, about half an inch thick. This mould is an intaglio picture, precisely resembling the finished copperplate.

A copperplate is made from the gutta-percha mould, by electrolysis. This part of the process is very slow, occupying perhaps a week or two. The copperplate thus obtained is called the matrix. It precisely resembles the original gelatin picture.

The plate from which the proof is to be printed is obtained by the electrotype process from the matrix. This is a slower process than the last, because the copper is much thicker. It occupies about three or four weeks.

The entire operation, therefore, occupies about six weeks. From the final plate, four or five hundred good impressions may be struck in the ordinary way. A considerable number of plates may be obtained from the matrix; also of matrices from the gutta-percha mould, and of gutta-percha moulds from the gelatin picture. Here, then, are the means of almost indefinite multiplication. The most elaborate subjects may be engraved by this process in as short a time as the simplest; the amount of detail in a photograph or photogalvanograph making no difference—for light, chemistry, and electricity do the work. The time at present required for any subject is a few weeks; the time frequently spent on engravings is two or three years.

THE STEREOSCOPE.—Before closing this article on photography, it may be well to dwell for a short time upon an instrument which creates, as it were, the pictured objects anew, and gives to them all the fulness and solidity which they exhibit in nature. Such is the *stereoscope*; and it may be stated with truth that it has more than doubled the pleasure and gratification derived from the beautiful productions of the photographic art. As a full exposition of the very simple optical principles on which the stereoscope is constructed would occupy more space than can be devoted to it, the Editor will give only the leading facts connected with it, together with brief directions for the taking of portraits or pictures to be seen in this instrument. Every one knows that by its agency two dissimilar pictures, of the same object or group of objects, placed on the same plane at a proper distance, are resolved into one; and that this exhibits all the attributes of the original, such as length, breadth, thickness, and relative distance.

The stereoscope—so named from two Greek words expressing *to see solid*—has given rise to much unpleasant discussion, with reference to the honor of its invention. There can be no doubt that Professor WHEATSTONE constructed the first reflecting stereoscope, and his memoir describing the instrument appears in the *Philosophical Transactions* for 1838, having been read before the Royal Society of London in June of that year. No claimant appears prior to this, and therefore there can be no doubt that to WHEATSTONE belongs the honor of having invented the stereoscope, or an instrument calculated to exhibit two slightly different pictures of the same object in such a manner as to produce the appearance of a single object, or group of objects, invested with the attribute of *solidity*. Sir DAVID BREWSTER, however, in the latest edition of his *Optics*, not only claims for himself the merit, to which he is justly entitled, of having invented the first really useful form of the *lenticular* stereoscope in 1844, but even prefers the claim of Mr. ELLIOT, an Edinburgh mathematician, to that of Professor WHEATSTONE, as the original inventor of the instrument. In the *Cosmos* for June, 1856, the latter distinguished philosopher indignantly confutes this statement, and cites Mr. ELLIOT's own admission, that in claiming priority of invention he labored under a mistake as to dates; having thought that a republication of WHEATSTONE's memoir which appeared in the *Philosophical Magazine* for April, 1852, was the first and original account of an instrument which had been recently invented. It appears, however, that Mr. ELLIOT is really entitled to the merit of having constructed a kind of lenticular stereoscope so early as in 1839; and the only question which remains unsettled is the claim of Professor WHEATSTONE to the prior invention of this form of the instrument also—a claim which he rests on certain expressions in a letter received from Sir DAVID BREWSTER himself. But the reader who desires fuller information on this subject is referred to the eighth volume of the *Cosmos*, and without entering further into the question of these conflicting claims, it may be stated as a fact beyond doubt that to Sir DAVID BREWSTER belongs the honour of having, in 1844, invented a lenticular stereoscope which, in convenience and portability, far excelled any other form of the instrument previously known, and first brought it into general use—an instrument which soon became very popular, and still contributes to the pleasure and gratification of thousands. Messrs. KNIGHT of London have, within the last few years, patented a new form of stereoscope, similar to BREWSTER's however, excepting the eye-tubes, which are dispensed with; their place being supplied either by a plano-concave and plano-convex lens of the same focal length, fixed to one another by their plane sides, or by prismatic ones.

The construction of the stereoscope is founded upon the faculty of binocular vision, or that property by which only one object is seen, notwithstanding that the form of it is depicted on the retina of each eye. On looking at any object it is evident that more of it is seen with the right eye on the right side than with the left, and equally the left eye observes more on the left side

than the right. Hence the picture presented to the right eye is slightly different from the view which the left takes of the same object; but by looking with both eyes all the parts noticed in the two monocular views are visible, and the pictures presented to both appear to each in the same spot, or overlap each other, so that only one object is seen, but a view of it slightly different from that which would be taken by one eye. It is partly owing to this circumstance, and partly in consequence of the greater or less convergence of the rays from the different points of an object in proportion as they are nearer or more distant, that the idea of solidity is realized; and this explains the cause of the difference observed between a picture of a bust or statue and the original, or of a landscape painting, and that which it represents.

On these simple facts the stereoscope was founded, it being considered that by representing two pictures of the same object exactly corresponding to those which would be formed on the retina of each eye, the head remaining stationary, a means of converging them into one, so that they might have the appearance exhibited by them in nature, could be devised. The difficulty of producing two such pictures had been a drawback to the project; and it was not till photography had obviated this inconvenience, by producing pictures of the object corresponding to those which the right and left eye respectively take of it from a given point, that its value was fully appreciated. On looking at the stereoscopic pictures singly with both eyes, no appreciable estimate of solidity or distance can be formed. If, however, the observer could contrive so to converge the optical axes as to throw the two pictures into one, then, indeed, all the solidity possessed by the originals would appear. It is needless to say, however, that very few are capable of doing this; and, when effected, it is with much pain to the eyes. But this, which is so difficult with the unaided eye, is what the stereoscope accomplishes—that is to say, it brings the corresponding points in each picture together, and, by their coincidence, gives the appearance of solidity and distance to them, just as in natural vision the binocular pictures are resolved into one view, leaving the impression of one or a series of objects, as the case may be, having length, depth, and breadth.

To simplify this a little more, if two stereoscopic pictures of the same object be mounted, so that the distance from their centres shall be equal to that between the pupils of the human eyes, and placed at one end of a box eighteen inches long, divided by a partition, and having two holes in the other end to correspond with the eyes of the observer; on illuminating the pictures only one will be discerned in consequence of the rays from each being refracted, first from the pupil of each eye at a slight angle to the retina, and thence in a straight line till the two lines meet or converge, at which point not two, but one picture will be seen, but this one will exhibit all the details of solidity and relative distance. Such was the instrument contrived by ELLIOT; but the distance from the eyes at which it was necessary to place the pictures to bring them to coincide, is reduced by the use of reflectors or lenses, as in the instruments of WHEATSTONE, BREWSTER, and others.

Mr. SUTTON gives the following explanation of the principle of the stereoscope:—

Let L, R —Fig. 414—be the eyes of a spectator; A, B, C , lamp-posts of different heights, having lights, or luminous points, A, B, C , at the top. Draw the visual rays,

Fig. 414.

LA, LC, LB, RA, RC, RB . Cut them by a vertical plane, PQ , parallel to the line which joins L and R . Then the points a, c, b, a, c, b , where the visual rays pass through this plane will be the images of A, B, C , as seen from the stations L and R , PQ being supposed to be the plane of a perspective picture. If the plane, PQ , be placed as shown in the figure, so that the perspective view as seen from L may be completely exterior to that seen from R , the pictures will be as represented on a card beneath L and R in the lower part of the figure.

Now, if the perpendicular distance between L and the plane PQ be such that the points a, b, c can be distinctly seen by an eye at L ; that is to say, if this perpendicular distance be not too short for distinct vision, and if the card, PQ , be placed before the eyes, as in the figure, the right picture being cut off from the left eye and the left picture from the right eye by a partition, as shown, then instead of seeing two pictures, abc, abc , only one image will be seen, and that one image will appear to be the lights, A, B, C , in their natural position, and at their true distance. For when the left eye is directed to a along the line La , the right eye is directed to a along the line Ra , and the optic axes La, Ra , would meet at A , so that the spectator, instead of seeing two images, a, a , upon a plane, PQ , sees one image, A , at the true distance and in the true position of the light, A . Similarly with respect to the other images, b, c, b, c , which combine and produce single images apparently at B and C .

VOL. II.

It is evident that the perpendicular distance of PQ from L or R , which call F , will depend upon the size of the angle, ALB or ARB ; for the smaller that angle is, the farther the plane, PQ , may be placed from L and R , and therefore the more easy it will become for the images a, b, c , to be seen distinctly by persons of ordinary vision. Most persons can see a thing distinctly at a distance of eight inches. If then $F = 8$, the angle ALB may be about 16° .

Now suppose that at each of the stations, L, R , a photographic camera is placed, the lens of which is eight inches focus, and adjusting these cameras with their axes strictly parallel, take the pictures of A, B, C , including an angle of 16° . Then when these pictures are properly mounted they will be identical with the perspective views of A, B, C , upon the plane PQ ; and if placed in a box having a partition in the middle and holes to look through at P and Q at a distance of eight inches from the pictures, the spectator on looking through the holes will perceive a single image of the points, A, B, C , at their true distance, and in their true relative positions.

A box so constructed may be called a *simple stereoscope*, because it does not involve the use either of lenses or reflectors, and the pictures properly taken and viewed in it have the inexpressible charm of truthfulness.

Of what use then, it may be asked, are lenses and reflectors? In the first place, the simple stereoscope, when adapted to persons of ordinary sight, does not include an angular field of more than 16° ; which is in general too small. A photographic picture should include at least an angular field of from 25° to 30° . This can only be effected by bringing the pictures as near to the eyes as five inches, at which distance most persons find a difficulty in seeing them distinctly; but this difficulty is overcome by placing a *whole* lens of five inches focus in each of the holes L, R , and viewing the pictures—which must be taken with a lens of five inches focus—through them.

Reflecting Stereoscope.—Fig. 415 represents the stereoscope of WHEATSTONE. It consists of two plane mirrors, AA , so adjusted as to form an angle of 90° with each other. They are fixed by their common edge against an upright, B , in such a way as to reflect the images placed in the side-frames, EE , fixed on the

Fig. 415.

upright boards, DD . The latter are attached to the sliding-boards, CC , movable from either end by the wooden screw, L , formed with a right and left hand thread for that purpose.

To see the pictures by this instrument, the observer

4 X

must stand before the mirrors, having the right and left eye respectively before the right and left hand mirror; then, on moving the frames EE , by the screw rl , backwards or forwards, the reflected images will be made to coincide at the optic axes and produce a single image of the same apparent magnitude as that observed. When properly executed pictures—such as are taken in a binocular camera, and which are seen with the same inclination of the optic axes—are introduced, the instrument may be simplified by omitting the screw and movable boards, the side ones being fixed in their proper places.

Mr. SUTTON, discussing the subject of the reflecting stereoscope, says:—Referring again to Fig. 414: if the visual rays are cut by a plane, $p q$, instead of $P Q$, the

Fig. 416.

pictures will be larger than before, and instead of being entirely exterior one to another, will overlap, and be, as it were, mixed together. But if the pictures be taken in cameras placed at L and R , with lenses of focal lengths Lm or Rn , having their axes parallel, and then by means of reflectors the images of the pictures so taken be thrown into their proper positions on the plane, $p q$, and these images viewed by eyes at L and R , a truthful solid image will be produced, as in the former case; because the left eye will not then see the picture from the right station, nor the right eye that from the left station. The principle of this arrangement is exhibited in Fig. 416, where DE , EF are the reflectors placed at right angles to each other, and ab , ba the pictures at right angles to the dotted line, or base, MN , passing through the point E , the distance of the reflectors from that angular point being equal to Lm or Rn , and therefore to the focal length of the lens with which the pictures are taken. The distance of the middle points, m, n , of the pictures from the dotted base, is half the distance LR . The pictures are taken in a nonreversing slide, so that their images on the plane $p q$, as seen in the reflectors, are not reversed; this is an important point to attend to. The image of the left hand picture is amb ; that of the right hand

picture bna , the lines, $p b$, $q a$, being separated for the sake of distinctness, but in point of fact the images lie on the same plane. The left eye cannot of course see the image of the right picture, and *vice versa*, so that the images overlapping produce no confusion. The image of each picture and the picture itself are symmetrically situated with respect to the reflector by which it is viewed.

All this being understood, the mode in which the instrument acts will now be intelligible. A pencil from b in the left picture, after reflection at the left mirror, DE , enters the left eye as if it had come from the point b on the line $p b$; the point b , is therefore seen by the left eye in the direction Lb . Similarly, a pencil from b in the right picture, after reflection at the right mirror, FE , enters the right eye as if it had come from the point b on the line $q b$; the point b is therefore seen by the right eye in the direction Rb . These two lines, Rb , Lb , are the instantaneous directions of the optic axes, and being produced they meet at B , which is the true position of the object, B . Similarly with respect to the other objects, A, C . Therefore by means of the reflecting stereoscope a true representation is afforded in natural relief and actual distance of the objects in the picture.

The reflecting stereoscope is not open to any single practical or theoretical objection. As an optical instrument it is *absolutely perfect*, being subject to no defects of distortion or aberration. For any scientific purpose, therefore, the reflecting stereoscope should always be preferred to the other. The reflectors may be made of polished speculum metal if objection be raised to glass mirrors, and the pictures may be taken simultaneously in a camera with double lenses two and a half inches from centre to centre.

The Lenticular Stereoscope.—The best construction of this instrument for exhibiting paper positives is shown in Fig. 417, which scarcely needs explanation.

The *whole* lenses fixed in the front of the box are placed two and a half inches from centre to centre, and should not be less than one inch in diameter. They should be five inches focus, and achromatized meniscus lenses with the hollow side outwards; in fact the same lenses as those used for taking the pictures, which may

Fig. 417.

be unscrewed from the camera, and screwed to the stereoscope. The back of the solid box should have holes in it as represented by the dotted lines, and also a partition in the middle. The orifices should be two and a half inches from centre to centre, and their dia-

meter determined by trial—generally about one inch. The inside of the front box should be properly blackened. The picture may be either square or circular, mounted two and a half inches from centre to centre, and about two and one-fourth inches in diameter. By the centre of each picture is meant the point where the axis of the lens cuts it.

Brewster's Stereoscope.—The stereoscope, modified by Sir DAVID BREWSTER, is shown in its most popular form in Fig. 418. It is a box having an aperture at the bottom, but most generally at the front, as seen in the drawing; an aperture at the side allows the slide bearing the pictures to be introduced. In the two brass tubes, R, L, half or quarter lenses are fixed, so that their curved circumferences will be inwards, or nearest one another, for the purpose of aiding the eyes in bringing the pictures, or representation of them, to coincide at the point of convergence of the visual axes. The tubes are made to slide up and down to suit the focal lengths of different eyes. By adjusting the lenses, the observer, on looking through both, sees only one picture midway between the two, and exhibiting the object or objects in bold life-like relief. It is

Fig. 418.

necessary to have the central points of the pictures within two and a half inches of one another, as also the tubes, in order to correspond with the position of the eyes.

Stereoscopic Pictures.—To obtain two pictures in their proper position for the stereoscope by means of one camera, it is evident that the instrument must have two apertures, and that these must correspond to the position of the eyes. The stereoscopic camera is constructed on this principle, with two lenses in front, of the same focal length, two and a half inches apart, focussing glass, and other requisites, as in the ordinary instrument. BREWSTER, however, contends that exact pictures of natural objects cannot be taken by the cameras in general use, in consequence of the lenses being too large, and causing a distortion in all the lines and portions of the object which do not fall in

the centre of the picture. He further states that it is almost impossible to take true stereoscopic portraits with a single-lensed camera, owing to the difficulty of measuring the proper angle at which the two should be taken, and of the sitter maintaining the same expression. Instead of employing two lenses, he bisects one,

Fig. 419.

and employs the half in each aperture, with the view of obtaining better results; for, as he says, it is impossible to grind or polish two lenses, whether single or achromatic, of exactly the same focal length, even when the same glass is used for both the sections. To overcome this difficulty, the single lens must be bisected and ground to a circular form, and afterwards placed in the camera with their diameters of bisection parallel to one another as in Fig. 419.

When portraits or views are to be taken in the monocular camera for the stereoscope, WHEATSTONE makes the position of the camera dependent, not upon the distance of the object from it, but upon the distance at which the pictures are observed in the stereoscope. Thus, when they are to be viewed at a distance of eight inches, he directs that the two pictures should be taken at an angle of 18° ; that is, if the object be the centre of the circle of which its distance from the camera forms the radius, the pictures must be taken from points on this circle 18° apart. BREWSTER, on the other hand deduces the angle at which the portraits or views should be taken from the distance of the subject, and the angle which the distance between the eyes subtends at that distance. This angle he finds by the formula—

$$\text{Tang. } \frac{1}{2} \Delta = \frac{\frac{1}{2} d}{D} = \frac{1.25}{D}$$

d being the distance between the eyes; D the distance of the sitter, and Δ the angle which that between the eyes—two and a half inches—subtends. By this he finds the angle formed by the two directions of the camera, when the distance of the object from it is that specified, to be as follows:—

Feet.	Degrees.
1.....	11.54
2.....	5.58
3.....	3.59
4.....	2.59
5.....	2.23
6.....	1.59
7.....	1.42
8.....	1.30
9.....	1.20
10.....	1.12

When the distance of the subject from the camera is

one hundred feet, the latter should be placed at points in the circle of which this is radius four feet distant from one another; for one hundred and fifty, six feet, and so on.

To pursue the subject of the stereoscope through all its details, as exhibited in the tubular reflecting, the single and double reflecting stereoscopes, the opera-glass, reading stereoscopes, *et cetera*, is incompatible with the limits of this work; the student who may desire further acquaintance with the subject is referred to BREWSTER on the Stereoscope, or any of the works on optical science which are to be found in libraries. The following remarks will not be out of place:—

In printing stereoscopic pictures from a negative, taken in a double-lens camera by contact in the pressure frame, it must be borne in mind that the print requires to be cut in half and the pictures transposed, in order to bring the picture that was taken from the left station before the left eye in the stereoscope, and *vice versa*. If this be not attended to, a pseudoscopic effect is produced.

In printing stereoscopic transparencies by means of a lens, the following plan may be adopted:—A copying camera, rather more than double the length of the stereoscopic camera, is provided, and the lenses of the stereoscope are fixed in the middle of it. There must also be a partition dividing the camera in half lengthwise. In this way the left lens copies the left picture, at the same time that the right does the opposite. The negative must be placed with its back next to the lenses at one end of the box, and the sensitive positive plate in a common slide at the other end. The camera is then directed towards the sky, and the wet collodion process employed. An exposure of a few seconds is sufficient. The positive need not be divided and the pictures transposed; for, when placed in the stereoscope with its plane side next to the lenses, and a ground glass laid against the film, the pictures are in their right position to be viewed. By putting the lenses midway between the negative and positive, the positive becomes of the same size as the negative. The best lenses to employ are portrait ones, with a small stop between the back and front lenses in each.

In the stereoscopes and stereoscopic pictures commonly sold there are the following five serious defects:

1. The pictures are frequently taken in converging cameras, and then mounted upon the same flat surface.

2. The pictures are generally mounted so wide apart, that the most distant objects in each are wider apart than the distance between the centres of the eyes.

3. An attempt is made to obviate the evil produced by the above practice, by using *semi*-lenses in the stereoscope, which displace the images. This of necessity produces distortion, because straight lines are always represented by curves, when the outside part of a lens is used to view objects through, instead of the centre.

4. The displacement of the images is in general so great as to cause the optic axes to converge to points situated within two or three feet from the nose, instead of the true distance of the objects. The effect of this

is to make the solid picture look like a small model of the object, which the spectator could, if he chose, lay his hand upon, or touch with a yard measure.

5. The focal length of the lenses of the stereoscope is in general six inches, while that of the lenses in the camera is only four inches. This makes objects appear much smaller than they do in nature.

To sum up: The common stereoscope and pictures make objects look very near, very small, and distorted. The lenticular stereoscope, represented in Fig. 417, makes them look of their *true* size, at their *true* distance, and without perceptible *distortion*.

In the preceding it has been announced that the object of the stereoscope is to exhibit things precisely as one sees them in natural vision; that is, with eyes two and a half inches apart. But if it be thought desirable for any purpose to represent things as one should see them, were the eyes wider apart than two and a half inches, then the distance between the stations may be exceeded.

Mr. SUTTON of Jersey kindly supplied the Editor with some valuable matter for this monograph.

PLATINUM.—*Platine*, French; *Platin*, German.—Whoever attentively regards the progress of any science, and sympathizes with those whose labors are ardently directed to its development, must, considering the difficulties that have to be overcome, necessarily feel interested in every discovery which tends to give greater certainty to their researches, and enable them to deduce laws for its extension and simplification. On this ground the subject of the present article cannot fail to recommend itself to every chemical student, since to it in a great degree may be attributed the precision observed in the results of every well-conducted analytical research. Although numerous subjects had been investigated before the discovery of platinum, and well-based conclusions drawn from them, still the methods by which these investigations were conducted were most circuitous; and, in the absence of a metal like platinum, the stoichiometrical equivalents of bodies were frequently mere approximations that required to be rectified by more appropriate apparatus and modes of analysis. In the multifarious operations of fusion, solution, evaporation, and weighing, connected with the labors of the chemist, no other substance can bear comparison with platinum. The corrosive agents used, and the unconquerable power of affinity, affected more or less all the utensils which the operator could command previous to the discovery of this metal, so that when the most devoted care was bestowed upon any research the results did not indicate the truth, and could not be depended upon even when they were rectified by an approximate estimation of the amount of the error. It is not so now; for, unlike gold, silver, or porcelain, platinum stands the test of intense heat, and so enables the operator to determine the effects of temperature and chemical action on the most refractory bodies; resists the effects of the strongest acids singly; and from the facility it offers of being forged into every convenient shape—such as basins, crucibles, weights, and the like—it facilitates working in the laboratory to a surprising extent. But it is not to the student or chemical philosopher alone that platinum is

of advantage—the manufacturer likewise is benefited by it; thus, in the distillation of sulphuric acid it can hardly be replaced by any other material, and in the preparation of drugs and extracts nothing safer than platinum can be employed.

This metal is not very abundant, though distributed in small quantities over extensive districts, and in numerous and diverse localities. The first account of it with which Europeans are acquainted is that of ANTONIO D'ULLOA, who observed it in the auriferous sands of South America. This notice was published in 1736; but the *savans* of this country and of the continent could form no idea of its nature till 1741, when Mr. WOODS, an assayer of Jamaica, sent a portion of the ore to Europe. Among the metallurgists of South America, however, it was long known, and bore the name *platina*, a diminutive of the Spanish name *plata* for silver. This term must have been applied on account of its occurrence in bright polished grains, appearing in color and brilliancy like silver. At that period, however, nothing being known of its properties further than that it possessed great weight, it was regarded as having no value, and, therefore, any quantity which might have been collected was thrown aside as useless—in fact, it was put beyond the reach of the miner, by casting it into the deep rivers, lest they might use it to sophisticate the gold they collected. On this account a large quantity of platinum ore has doubtless been put out of the reach of present or future use for a considerable time to come. WOOD gave the first scientific account of it in a paper published in the *Philosophical Transactions* in 1750; and in 1752 its proportion in the platinum sand was determined by SCHEFFER. LEWIS wrote upon it in 1754; MARGGRAF in 1757; and since then researches upon it have been published by BERGMANN, VON SICKINGEN, MUSSIN-POUSCHKIN, FOURCROY, and VAUQUELIN, WOLLASTON, DESCOTILS, TENNANT, BERZELIUS, EDWARD DAVY, DÖBNER, and CLAUS; from which investigations resulted the discovery of palladium, rhodium, iridium, osmium, and ruthenium in the ore, and all alloyed with platinum.

LOCAL SOURCES.—The principal districts which afford platinum are those of Brazil, Peru in South America, and Antioquia in the North, also the slopes of the Ural Mountains. In Borneo, and in almost all the gold-washing districts throughout the world, traces of the metal have been detected. Along the coast of the South Sea, and on the Western slopes of the Cordilleras of the Andes, between the second and sixth degree of north latitude, platinum occurs; but the most productive washings are those of Condoto in the province of Novita, of Santa Rita or Viroviro, of Santa Lucia, of the ravine of Iro, and Apoto, between Novita and Taddo. The deposit of gold and platinum is found in alluvial ground at a depth of twenty feet; both metals are separated sometimes by picking out the grains of platinum ore, and, when this method cannot be conveniently adopted, by amalgamating the gold, by which process the platinum is left.

In the provinces of Matto Grosso and Mineas Geraes in Brazil, platinum is found in the alluvial deposits which

produce gold. The ore of these localities differs from that of Peru, being met with in grains of a globular form, and which exhibit a surface made up of small spheroidal protuberances strongly adhering together, the interstices being clean and even brilliant. None of the magnetic iron ore or small zircons observed in the Peruvian product are observable in it. It is, however, mixed with small radiated or fibrous grains of palladium.

The veins of manganese in the weathered syenite near Santa Rosa de Osos, in the Columbian province of Antioquia, afford platinum; and it has been obtained from the valley of the river Jacky in Saint Domingo. Like the platinum sands of Peru, the product of this district appears in brilliant rounded grains, as if polished by friction. It yields chromium, copper, osmium, iridium, ruthenium, palladium, and probably titanium. The total quantity derived from South America does not exceed eight hundred and fifty pounds annually, a product which is much inferior to the washings in the districts of the Ural Mountains where the metal is found. In 1819 a whitish kind of gold was detected in the mine of Neiwin Körner; but its nature was not ascertained till 1822, when platinum was detected in it. Platinum washings were established in 1824, and since that period considerable quantities are annually produced by them; they are situated on the Western slopes of the chain of mountains, and the ore is met in alluvial deposits partly, and in other localities injected into the greenstone and serpentine rocks. The chief workings are at Nischne-Tagilsk, Goroblagodat—Kuschwa—Nischne-Turinsk, where the metal occurs almost without gold; Bogoslawsk in important quantities; also at Slattoust, Werch-Isetsk, Newiansk, and Bilimbajewsk. In most of these washings the platinum ore constitutes from one-four-thousandth to one-fourteen-hundredth of the sand, and contains on an average about seventy per cent. of platinum. That from Goroblagodat yields eighty-eight per cent. Another ore, osmide of iridium, is also met with in small quantity in these districts, yielding on an average two per cent. of platinum.

Platinum is also found in greater or less quantities in other countries; for instance, in the Ratoo Mountains in Borneo, and in the gold sands found on the North of Ava, black magnetic particles are collected which yield twenty per cent. of the metal. The gold sands of the Rhine afford a small per centage of platinum; so also does the palladium from Wilhelm Works on the Hartz. It has been detected in the departments De la Charente and Deux Sevres in France, in Guadalcanal in Spain, and in Ohlápian in Hungary. According to PETTENKOFFER, all silver, unless subjected to a particular process of purification, contains traces of this metal; he found it in the gold reclaimed from the furnace slags of Munich. GUEYRNARD latterly detected it in the grey copper from the Department des Hautes Alps, and in the bournonite from Saint Arey on the Mure. RITTERSON observed it in the gold sands of California, and MALLET in the auriferous gleanings from the Wicklow Mountains.

Platinum, though invariably found in the metallic state, has never been discovered pure and unalloyed.

The annexed table exhibits a few analyses of the product from different localities:—

COMPOSITION OF CRUDE PLATINUM ORES.

	Berzelius.				Svanberg.		
	a.	b.	c.	d.	e.	f.	g.

The sample *a* in the foregoing table was a dark-grey ore from Nischne-Tagilsk in the Ural, which was non-magnetic; the sample *b*, from the same locality, but magnetic; *c* was from the washings at Goroblagodat in the same region, and perfectly non-magnetic; *d* was obtained from Barbacoas, and consisted of very large grains; *e* was from Choco, an ore freed from ferruginous particles as much as possible with the magnet; *f* from the river Pinto. This variety was classified into several subvarieties; thus, *a*, rounded grains, having considerable lustre and a color inclining to leaden-grey, of specific gravity equal 17.88; *b*, angular grains, of a light grey color and little lustre, of specific gravity 17.08; *c*, rough grains, somewhat yellowish, but having black points, specific gravity 14.24; and *d*, black shining grains, specific gravity 7.99. Of these, the *a* variety was analysed, and the numbers stand under *f* in the table. The results under *g* are of the osmium-iridium from South America.

Generally the ore of platinum is met with, as already stated, in small grains; but considerable masses of the metal have occasionally been discovered. The largest lump that has been found in America is retained in Madrid; it weighs eleven thousand six hundred and forty grains, or two pounds troy, and appears in size nearly equal to a turkey's egg. This specimen was found in 1814 in the gold mine of Condoto. A lesser lump was brought from Choco by HUMBOLDT, and presented to the cabinet of Berlin; it weighs one thousand and eighty-eight grains, or little more than two and a half ounces. Much larger masses of the metal have been found in the Russian territory already mentioned. A nugget of platinum, found at Nischne-Tagilsk, and still retained in the St. Petersburg collection, weighs ten pounds fifty-four zolotnik—9.2364 Prussian pounds weight—but its specific gravity is only 16.0. Another lump of nearly double the size of the former, was discovered in 1830 in the same works; it weighs twenty pounds thirty-four zolotnik Russian—equal to 19.684 pounds avoirdupois; and later, another mass weighing 22.744 pounds was found. In the royal mineral collection of Berlin is a piece of platinum ore which was presented to the cabinet by Count DEMIDOFF.

SCHUBART states that from 1822 to 1835 no less

than thirty-one thousand and seventy-two Prussian pounds of platinum were obtained from the Ural Mountains; in 1836 one hundred and eighteen puds two pounds, and in 1848 one hundred and fourteen puds, equal to three thousand nine hundred and eighty-seven and a half Prussian pounds were obtained.

PREPARATION OF PLATINUM.—When obtained directly from the ore the difficulty of preparing the metal pure increases according to the number of other components associated with it; if the platinum be alloyed only with gold, all that is necessary is to treat it at once with nitro-hydrochloric acid till the whole is dissolved, to remove the excess of acid by evaporation, and then produce the ammonio-chloride of platinum by the addition of chloride of ammonium. The terchloride of gold may be washed out of the yellowish-red crystalline salt by water. If other metals be united with the platinum, as in the samples of which the analyses have been given above, then the sand is alternately treated with strong nitric and hydrochloric acids, till all the copper, iron, lead, and silver, manganese, *et cetera*, are removed; the washed residue is then acted upon with *aqua regia* till the whole of the metals dissolve. A moderately dilute solution of sal-ammoniac is now added to the clear filtered liquid, which should, however, be as free of acid as possible, and the precipitated double salt of ammonia and platinum collected, washed well with cold water, dried, and reduced to the metallic state. The latter operation is effected by gently heating the mass at first, and indeed till the whole of the ammoniacal salt is expelled, and subsequently bringing it to a strong red heat. The residue now will be pure metallic platinum in a very finely-divided condition, or, as it is ordinarily termed, *platinum mohr*—*platinum black*. The rhodium, palladium, osmium, and iridium, provided a little nitric acid be added previous to precipitation, remain in the mother-liquid, and can be recovered subsequently.

The product thus obtained may be again dissolved in *aqua regia*, and reprecipitated as before, when any palladium which might have been thrown down before will be removed in the liquor and washings of the ammonio-platinum salt. The metal obtained by heating to redness the last-mentioned compound, or by

electrical precipitation, by means of a plate of zinc, from an acid solution of the bichloride of platinum, is—after washing and drying, and subsequently heating to redness—in the form of a black slightly adhesive mass, which may be reduced to a powder of the same appearance, capable by pressure and friction of being made to assume the metallic lustre.

PROPERTIES.—In its purity platinum has a white color, nearly approaching to that of silver. Its density is, with the exception of iridium, the greatest of any known body. Several results nearly coinciding have been arrived at regarding its weight, among which are the following:—CLARKE found the specific gravity of hammered platinum to be 20·875; BORDA, 20·98; SICKENGEN, 21·061; WOLLASTON, 21·25; BERZELIUS, 21·45; KLAPROTH, 21·74; and CLOUD, at 62·6°, 23·543. When compressed by welding, and drawn out into thick wire, it indicated 21·4, and after being still further extended, 21·5. It is infusible at the highest temperature of a wind furnace, though capable of being welded like iron at a white heat; the temperature of the oxyhydrogen blowpipe, however, as also that of the flame of a powerful voltaic current, readily melts and even boils it, dispersing a portion into vapor, which appears to burn and form an oxide of the metal. DUMAS observed that it becomes harsh and brittle when heated powerfully in contact with charcoal, owing to its combination with a little carbon, or silica, or phosphorus. Platinum is very malleable, and, therefore, can be beaten out into very thin plates, and drawn into wires one-two-thousandth of an inch in diameter; and with proper means, such as inclosing it within a silver wire, into wire only one-thirty-thousandth of an inch. The least admixture of iridium deprives it of this quality to a greater or less extent. Air and moisture have no effect upon the metal even in the heat; unlike gold and silver, sulphur and mercury do not injure it even when intensely heated. Nitrate of potassa, however, and potassa and lithia, at a high temperature, oxidise it; but it remains uninjured by the strongest simple acids. The combination of hydrochloric and any other of the mineral acids dissolves it readily; so likewise chlorine water, or a mixture of a chloride or nitrate, and of nitric or hydrochloric acid, and in every instance a bichloride— Pt Cl_2 —of the metal results. With phosphorus, arsenic, antimony, bismuth, cadmium, tin, and lead, platinum forms alloys at moderately high temperatures; and if the heat be increased it combines even with silver and copper, in which state it is sometimes readily dissolved by nitric acid, although this has no action upon it in its purity. Platinum is not such a good conductor of heat and electricity as other metals of less density. DESPRETZ has given the following numbers indicative of the comparative conducting power of the metals, assuming that of gold to be equal to one thousand:—

Gold,	1000
Platinum,	981
Silver,	973
Copper,	898
Iron,	374
Zinc,	363
Tin,	304
Lead,	180

WOLLASTON has shown, however, that the above results are untenable, since, according to a simple experiment devised by him, if rods of the several metals of equal length and weight be covered with wax, and equally heated at one end, the wax on the copper rod will have melted at the distance of 3·5 inches, on the silver at 2·5 inches, and on the platinum and palladium only at the distance of an inch. Its expansion is less than any of the other metallic bodies, being only 0·0009918 between 32° and 212°, or one thousand one hundred and eighth of its bulk. Its specific heat, according to DULONG and PETIT, is 0·03414.

Such are the principal properties of forged platinum, or of the metal made into utensils, wire, or thin leaves; but in its other states, such as platinum black and spongy platinum, it exhibits other properties, which are highly interesting and characteristic of this metal.

Spongy platinum is obtained, as already intimated, by heating the ammonio-chloride of platinum to redness; and provided the salt be pure, no other substance will contaminate it. The substance appears of a dull grey color, soft and porous; when ignited strongly it adheres together, and by subjecting it to pressure with hard bodies, it is made into the form of laminæ, having the metallic lustre. The interest attached to this body arises from the fact that without any apparent change it induces the combination of gases with one another, or the oxidation of bodies, to a remarkable extent. DÖBEREINER was the first to bring this remarkable fact before the consideration of the scientific world, by showing that a stream of hydrogen and of oxygen gases directed upon it are inflamed merely by its contact, and that hydrogen alone is capable of making it red hot. DULONG and THENARD showed that this metal, in the more compact form of fine wire and foil, is capable of inducing the union of oxygen and hydrogen in a limited degree, and FARADAY has shown what precautions are necessary to be observed to insure success in the trial—namely, cleanliness of the metal effected by fusing potassa on its surface, and after washing in water, rinsing it in hot oil of vitriol, and again with water. In this state platinum foil will act upon a mixture of the two gases in the proportion of one volume of oxygen and two of hydrogen, so as to speedily become red hot. Contact with the skin, a cloth, or mere exposure for a few days divests it in a great degree of this property; so likewise do sulphide of hydrogen, carbonic oxide, and olefiant gases. The explanation given of this remarkable effect is, that it results from the concurring influence of two forces, namely, the self-repulsive energy of similar gaseous particles, and the adhesive attraction exerted between them and the platinum. Each gas, repulsive to itself, and not repelled by the platinum, comes into the most intimate contact with that metal, and both gases are so condensed upon its surface that they are brought within the limits of their mutual attraction, and so combine.

Spongy platinum has, besides the power of causing the ignition of oxygen and hydrogen gases, that of condensing vapors upon its surface and in its pores to a

surprising extent. Thus, when exposed to the air, ordinary freshly-prepared spongy platinum absorbs oxygen gas to the extent of many times its volume, but little or no nitrogen. In this state it induces the combustion or oxidation of several gases of a combustible nature, and also of liquids. Thus it is that hydrogen is burned and oxidised into water, and alcohol into acetic acid. There are several forms of finely-divided platinum, which exhibit greater power of condensation of gases, and so of effecting chemical changes with greater force than spongy platinum. Such is the product resulting from the combustion of bibulous paper which had been saturated with a solution of bichloride of platinum and dried, and that produced by voltaic action in an acid solution of bichloride of platinum by a bar of zinc; but the most remarkable for this effect is the platinum black of LIEBIG. It is prepared by boiling bichloride of platinum solution with an excess of potassa or carbonate of soda, by which the heavy metal is reduced to the state of a proto-compound, and on now pouring alcohol gradually into the solution, a precipitate of a black color falls, which is the compound in question. It is in a finely-divided, and probably in a more amorphous state than any of the other compounds. When this body is well washed and dried, it takes up as much as two hundred and fifty times its volume of oxygen, and if absolute alcohol be dropped upon it in this state ignition immediately takes place. The combustible gases are quickly inflamed by it, and spirits of wine energetically acetified. As with the others, exposure for some time to moist air, ammoniacal vapors, or sulphide of hydrogen gases, destroys in part or wholly its power of effecting these changes; but washing with an acid and water, or heating it to redness, restores its usual properties again. LIEBIG's platinum black, however, when treated with dry ammoniacal gas is rendered red hot, and considerable quantities of the vapors are absorbed.

Platinum is capable, under certain conditions, of uniting with most of the non-metallic elements, and forming combinations that enter into new formations of the binary saline class; and with the metallic bodies in the form of alloys, but which are of little importance. The chemical symbol of platinum is Pt., and its combining weight 99.

METALLURGY OF PLATINUM.—The complex nature of the crude ore of platinum has attracted considerable notice, and has led chemists to publish several methods for its preparation, as well as for the estimation of the associated bodies.

Whatever method is chosen, the crude ore is submitted to a purifying process before the business of extracting the platinum commences. For instance, the gold which may be mixed with the particles of platinum or alloyed with it, is separated usually by adding mercury, and removing the residual matter from the amalgam. Particles of titanate of iron may be abstracted from it by the magnet, or if the ore itself should be partly attracted, the sortment will afford different qualities of ore. At St. Petersburg, where the platinum of all the ore found in the Ural is extracted, the following process is pursued:—Into each of thirty open platinum basins capable of holding eight pounds,

that are ranged on a sand-bath covered by a glazed dome with movable panes, and the whole surmounted by a ventilator which carries off the liberated acid vapors, a certain quantity of the material is introduced, and a mixture composed of three parts of hydrochloric acid 42° Twaddell, and one of nitric at 73° Twaddell, poured upon it. The whole is then heated during eight to ten hours, or till the evolution of red fumes ceases; and after allowing the undissolved matter to subside, the liquid is decanted into a large cylindrical vessel, the residue is washed with water, and the washings added to the first liquor. The undissolved matter is treated with further quantities of acid till the whole becomes soluble, and the liquors commingled in the common receptacle already mentioned. Aqua regia to the amount of from ten to fifteen times the weight of ore operated upon is required, according as the granules of the ore are smaller or larger in bulk. Moderately dilute aqua ammonia is now added to the acid liquor in the glass vessel, when a precipitate occurs, and on its subsidence the supernatant liquor is decanted into other vessels and evaporated to about one-twelfth in glass retorts, embedded in a sand-bath; on allowing this liquor to cool the double chloride of ammonium and iridium crystallizes out in the form of a dark purple powder, which is separated, and the mother-liquor evaporated to dryness in porcelain vessels, the residue calcined and treated anew like fresh ore. The precipitate obtained in the first instance is dried, calcined, and heated to redness for obtaining the metal in a spongy state. In order to agglomerate this sponge, it is pounded in a bronze mortar, the powder passed through a fine sieve, and the product introduced into the mould in which the ingot is to be formed. Here it is compressed with a rammer which is forced in by a coining press, and when reduced to the proper size, it is removed from the mould and baked for thirty-six hours in a porcelain kiln, after which it may be forged with ease, provided the iridium had been separated from it. The ingot of platinum contracts to the extent of one-sixth or one-fifth of its volume during the roasting in the oven. The cost of preparing platinum is estimated to be about twenty-five to twenty-seven shillings per pound in Russia.

WOLLASTON's method, of which the preceding is a modification, is the most perfect, and that best calculated to yield a pure metal. VAUQUELIN struck upon the same, but in its details that of the former is the most complete. For the preparation of the pure metal, the platiniferous grains are treated with aqua regia and chloride of ammonium, as in the preceding case; only, to prevent the solution of the iridium it is necessary to dilute the acids, so that it will remain in the residue. It is well to reduce the strength of the hydrochloric acid with an equal quantity of water, and also that the aqua-fortis and muriatic acid be quite pure. WOLLASTON has indicated that a quantity of hydrochloric acid, equivalent to one hundred and fifty of dry acid, and as much nitric acid as will contain forty parts, is sufficient for the solution of a hundred parts of the platiniferous matter; but as it is best to have an excess of the ore, one hundred and twenty parts of the latter should be employed. The action of the compound acid should

take place slowly, and a very gradually increasing temperature be applied till the operation be completed, which happens in about four days. After this the contents of the vessel are allowed to repose, in order that the iridium suspended in small particles in the liquid may deposit; this done the clear solution is to be drawn off, and after the separation of any subsided matter, forty-one parts of chloride of ammonium are added, when the yellow crystalline chloroplatinate of ammonia falls. This precipitate weighs one hundred and sixty-five parts, and contains sixty-six parts of platinum. Palladium, iridium, rhodium, ruthenium, osmium, gold, silver, iron, and any other foreign matters, are all or in part contained in the mother liquor from the last precipitate, together with eleven parts of platinum. To obtain it the whole of the metals are precipitated by means of a clean plate of zinc or of iron, the metallic deposit well washed, redissolved in aqua regia as before, and the platinum thrown down with chloride of ammonium, after having added one part of strong hydrochloric acid to every thirty-two parts of the liquor, with the view of holding the palladium and lead from falling down with the yellow platinum salt. By a later method, WOLLASTON neutralizes the acid solution with carbonate of soda, and precipitates the palladium from the liquid with the cyanide of mercury, in the form of whitish flakes. When this is removed by filtration, the platinum may be removed from the mother-liquor by the addition of forty-one parts of chloride of ammonium.

The precipitate from the first liquor, as well as that from the re-solution of the residuary matter in aqua regia, must be as well washed with cold water as possible, quite free from the chloro-iridate of ammonia; it is then to be dried carefully by pressure between folds of bibulous paper or other absorbent matter. After the whole of the moisture is dispersed, the substance is introduced into a black-lead crucible, and subjected to a temperature merely sufficient to expel the ammoniacal salt and the radical of the platinum compound. Should the heat be raised too high, it would cause the agglutination of the metal, so as to render its subsequent compression into ingots difficult, at the same time that it would decrease its welding power. The loose platinum powder is next rubbed between the palms of the hand very gently, sifted through a linen cloth, and the coarse particles that remain behind reduced in a wooden dish with a pestle of the same material, with as little force as possible. This portion is then sifted like the rest, and the fine powder, which ought not to exhibit any metallic lustre, or the finer parts, may be separated by elutriation and decantation. Having sufficiently reduced the mass, it is mixed with water to a pastelike consistency, and introduced into a brass mould or cylinder 6.75 inches high, 1.12 inch wide at the top, and 1.23 at the bottom, which is inclosed by a steel stopper that enters it to the distance of a quarter of an inch, having the inner face smeared with grease. The whole is now wrapped round with bibulous paper, and placed in a vessel of water so as to fill it with the liquid, when the metal sinks and fills every portion of it equally, and cavities in the ingot are avoided.

A piece of bibulous paper is now laid on the top of

the platinum, and then woollen cloths, and the excess of moisture removed by pressing the contents of the cylinder by a wooden pestle forced by the hand. The cloths and paper are removed at this stage, and a disc of copper substituted, the paste having sufficient consistency to allow the mould to be placed horizontally in a press, to be condensed preparatory to its forging. The kind of apparatus which WOLLASTON invented is represented in Fig. 420. After the pressure is sufficiently exerted, the cylinder is opened, and the ingot, shaped in the form of the cylinder, taken out without

Fig. 420.

danger of breaking in the hands, and heated nearly to redness in a charcoal fire, in order to drive off moisture, burn the grease, and give it greater compactness. It is now laid endwise on a support of clay, which is strewn over with quartz sand, and introduced upon the bars of a wind furnace, but so that it will be two inches and a half above them. A brisk coke fire is to be supplied, and while exposed to the intense heat of the fire the cylinder is covered with a crucible of very refractory clay, but in such a way as not to touch the metal. Twenty minutes' ignition is given, but the intensity of the temperature is moderated during the last few minutes. The defect of blistering so frequently observed in platinum arises from improper treatment of the metal at this stage, and to remedy it the highest possible heat of a wind furnace should be applied. Whilst still red hot the ingot is taken from the furnace, placed upon the anvil endwise, and struck with a hammer repeatedly. Should it bend under this treatment, it must not be straightened by striking it in a horizontal position, but the blows must be directed on the edges as to rectify the bend, and so still preserve it straight. After the ingot is sufficiently condensed by this means, it is in a position to bear forging and working into any desired shape, like any other metal. To separate the ferruginous scales with which it may become coated during its exposure in the furnace, the ingot must be coated with a mixture of equal parts of borax and cream of tartar, in a moist state; placed upon a platinum support; a refractory crucible inverted upon it, without touching; and then introduced into the furnace, and there brought to a full red heat. It is next withdrawn, and immersed in a bath of dilute sulphuric acid, which has the effect of dissolving the incrustated flux and any adhering iron. The ingot may now be hammered out into foil or drawn into wire as required. WOLLASTON found the specific gravity of the metallic powder

compressed in the mould to be 10·0, after strong ignition 17·0 to 17·7, after hammering 21·25, when drawn into thick wire 21·4, and into fine wire 21·5.

The manner of manufacturing crucibles and such vessels designed for chemical purposes, is to introduce the powder platinum into a steel mortar of the intended shape of the crucible, and then the stamp is forced in by means of a press or by repeated blows of a hammer. On removing the steel base of the mortar, the cylinder of platinum may be forced out by carefully pressing the stamp further inwards. The cylinder is then carefully ignited in a platinum crucible, at first in an ordinary assay or air furnace, and afterwards in a blast one to the highest degree, after which it may be beaten on the anvil.

The following directions for mending platinum vessels in use in the laboratory may not be uninteresting. An injured platinum vessel may be mended in the following manner:—The cracked or perforated vessel is thoroughly cleansed, either by fusing potassa in it, and then treating it with an acid, or by scraping the part and afterwards filing down the asperity of the surface; a clean piece of foil of a thickness suited to the vessel is then laid on the defective part, and the whole heated to bright redness in a smith's forge, after which the article is removed to the anvil as quickly as possible, and while yet red hot, struck quickly with a hammer to weld the piece to the body of the vessel. After the adhesion of the two, the part may be beaten out after successive heatings, to give it a smooth surface. To renovate a crack on the edge of a crucible, a narrow bent strip of platinum foil is suspended over it, and pressed as near as possible to the side of the vessel; the whole being then heated in the flame of a blowpipe lamp to whiteness, and while in this state struck on the pointed end of the anvil lightly, but quickly, with the hammer. The part may be smoothened by repeating the heating, and striking it whilst hot on the anvil. When the injury is in the form of a perforation, a platinum wire is selected of the size of the hole and struck flat at its end; this is then passed through the vessel, cut off close at the other side, and the end flattened by a few strokes of the hammer. The vessel is now heated in the fire till it becomes nearly white hot, and struck in the manner directed above, when a secure welding takes place. Should the hole be large, a piece of platinum plate of the suitable size is taken and secured to the edge of the vessel by a number of platinum rivets; it is then transferred to the fire, and when sufficiently heated beaten on the anvil with the flat smooth hammer. In either of these cases the new joint is indiscernible when properly effected.

Platinum crucibles and vessels are liable to injury from the following agents:—Nitrohydrochloric acid, chlorine water, a mixture of hydrochloric acid with chromic acid or its salts, or with a peroxide, such as manganese, attack the metal and readily dissolve it. Lead, bismuth, zinc, or any other metal heated in a platinum vessel to its melting point, or nearly to that degree, alloys itself with the platinum, and either produces a hole at once or an alloy, which is acted upon by acids. The most destructive of this class are those of arsenic and antimony; and hence, not only must the

operator carefully avoid heating these to redness in a platinum vessel, but likewise their oxides and the salts which they form with other bases. This is more especially the case, if charcoal or any carbonaceous matter be present that would cause a reduction of the arsenical or stibic compound. Many other oxides of an easily reducible nature injure crucibles when carbonaceous matters are not carefully excluded. This also applies to phosphoric acid and its salts, since in contact with carbon at a high heat reduction takes place, and a brittle and easily fusible phosphide of platinum results. Alkaline sulphides or cyanides should not be fused in platinum vessels, as these agents dissolve considerable quantities of the metal. Silicium at a high heat unites with platinum, rendering it brittle and disposed to crack; hence vessels of this metal ought never to be heated exposed in an open fire; they should be protected by an outer earthen crucible, contact of the two being prevented by calcined magnesia. Potassa, soda, lithia, and their nitrates, when fused in a platinum vessel, oxidise part of the metal, which is dissolved in the form of an alkaline platinate. This is more particularly the case with lithia. Sulphur does not affect it unless arsenic or some other deleterious body be present, neither has pure phosphoric acid any action upon it.

The purity of platinum vessels is tested by treating them with the simple acids—hydrochloric and nitric—in succession, and examining the acid liquor to ascertain the nature of the dissolved matter, should any exist. It frequently happens that platinum vessels in frequent use in the laboratory get tarnished, in which case they may be again rendered bright and clean by smearing over their surface a paste made with equal parts of pounded borax and cream of tartar—bitartrate of potassa—and fusing it in the heat. On immersing the vessel subsequently in a bath of pure dilute sulphuric acid, all extraneous matters are dissolved, and it presents a clean bright surface.

Platinum is rarely applied to the purposes of the jeweller, silver being preferred; indeed, its chief use, except in Russia, where it is coined, is for chemical apparatus and philosophical instrument making, in the construction of electrical batteries, dentistry, *et cetera*. It is chiefly absorbed in the construction of stills for sulphuric acid rectifiers, pans, stills, and digesters employed in the manufacture of drugs and many of the purer chemical preparations. Like silver and gold, this metal, when it is past use in the various forms in which it is manufactured, is carefully collected and returned to the platinum founders, to be again worked up into the same or other articles. It is usual to allow half price for returned platinum; but this standard is evidently too low when compared with the price of the manufactured goods. The amount of platinum manufactured and traded with annually averages from five thousand eight hundred to six thousand three hundred pounds troy, of which North and South America yield about seven hundred to eight hundred and fifty pounds, and Russia five thousand one hundred to five thousand four hundred and fifty. What is obtained from other sources is small, and does not enter into the foregoing statistics.

ALLOYS.—Platinum forms alloys with several metals, the most interesting to the artisan being those which it yields with zinc, iron, lead, copper, and silver *with zinc*. When one and a half to two parts of zinc are mixed with one part of spongy platinum and heated, vivid combustion of the mass is observed to take place, even before it has attained a red heat. The compound mass has a bluish-white appearance, acquires considerable hardness, and is easily melted, the zinc becoming an oxide if air be admitted. With a quarter of its weight of zinc, platinum is rendered brittle; and zinc, with about a twentieth of its weight of platinum with iron. A powerful heat is required to effect the combination of iron and platinum, which, however, constitute a very hard alloy, scarcely acted upon by the file, and somewhat malleable. FARADAY and STODART have made several experiments upon the alloys formed from steel and platinum. Those averaging from four to nine parts of steel to one of platinum, are characterized by their close texture, which enables them to take a high polish, and by their not tarnishing in the air. An alloy of sixty-seven parts of steel and one of platinum, they found to be well adapted for the manufacture of cutting or edged tools. One part of platinum and a hundred of steel is a metal less hard than silver steel, but tougher. With one of platinum and two hundred of steel, a metal was formed which BRÉANT recommends for the manufacture of razors.

With Lead.—Alloys of lead and platinum have few peculiar or striking characteristics, except that they melt readily, possess a color approaching to purple, and break or split under the hammer.

With Copper.—A sustained white heat is required to induce combination of copper and platinum. In equal quantities they melt, and form a golden-colored alloy very malleable; with one-sixth to one-twenty-fifth of platinum, the color of the alloy is between pale red and rose red; the metal works well under the hammer, and takes a good polish, but it is a little duller in its aspect than pure copper. An alloy of copper and platinum has been introduced for mounting telescopic and other lenses. COOPER prepared an alloy of seven parts of platinum, sixteen of copper, and one of zinc, which is similar to sixteen carat-gold, is very extensible, and remains unaffected by strong nitric and sulphuric acids.

With Silver.—Silver, when combined with platinum, becomes darker in color, less malleable and harder than it is *per se*, and in proportion as the admixture of platinum is increased, its melting point becomes higher. Equal weights of silver and platinum give a hard dull-hued alloy, very brittle under the hammer; when the proportion of silver is more than five per cent. and cupelled with lead, no brightening occurs. Sulphuric acid dissolves part of the silver from the alloys rich in this metal, but nitric acid does not effect the analysis of both metals, as the solution contains both silver and platinum.

With Gold.—Platinum unites with gold, but when the proportions are equal it requires the strongest heat of a wind-furnace to effect the fusion; and when the combination of the two metals in the ratio of three of gold to seven parts of platinum is essayed, the tem-

perature of the oxyhydrogen blast is necessary. The alloys in every instance are characterized by having a lighter color than gold, a great density, and when the gold averages a sixth to a fifth of the weight, considerable elasticity.

COMBINATIONS OF PLATINUM.—This metal is capable of uniting with most of the non-metallic elements; with several of them it readily combines, whilst with others the conditions requisite to effect the combination are varied. In a practical point of view, however, these are uninteresting, as no particular application of them has been made, with, perhaps, the exception of the bichloride, which is in continued request in the laboratory, and in some cases in the potter's art, for producing bright steel greys. Some of the compounds thus produced, more especially the chloride, enter into the formation of other well-marked bodies of a compound saline nature, wherein the platinum compound remains intact, and occupying as it were the part of a radical in the new salt.

It would be useless to describe these combinations here, the more so as they serve but little the purposes of the manufacturer. The bichloride of platinum, which is the most useful of the class referred to, may be prepared as stated when speaking of the preparation of platinum, namely, by treating the metal with aqua regia containing an excess of hydrochloric acid, and evaporating till all the free acid is removed. The salt has a dark red crystalline appearance, is deliquescent, and gives with water and alcohol—in which menstrua it is soluble in all proportions—dark red solutions. Its symbol is $Pt Cl_2$, and its atomic or equivalent weight one hundred and seventy.

POTASSIUM.—*Potassium*, French; *Kalium*, German and Latin.—The discovery of this interesting metal was made as lately as the commencement of the present century. The compound nature of the alkaline base—potassa—had long been suspected, though never previously proved to a certainty. Nor were philosophers agreed as to its supposed constitution; for while LAVOISIER suspected it to be a true metallic oxide, the more generally received opinion was, that nitrogen was an ingredient in its composition. The proof of its compound nature, until then merely hypothetical, was reserved for that distinguished philosopher, Sir HUMPHREY DAVY, who in 1807 succeeded by means of a powerful voltaic battery in separating potassium, with the metals of the other alkalies and of the alkaline earths, from their combinations. This, unlike the great majority of discoveries at that period, was not the result of accident, but of true scientific reasoning, and was confidently expected to follow the application of that agent, the extraordinary powers of which had been until this period so little understood and investigated, but which has since been so beneficially applied to the wants of mankind. Lord BROUGHAM, referring to the discovery of this and the other alkaline metals, remarks, that he could well remember that in discussing the subject, they used to look forward with perfect confidence to the analysis of those bodies which had hitherto proved the most stubborn, and expected soon to find the fixed alkalies, and even the alkaline earths, shown to be oxides, as by some very imperfect experiments they

had at one time been supposed to be proved. The discovery was not long delayed. In October, 1807, DAVY, after in vain endeavoring to decompose the alkalis when mixed with water—for then he could only decompose that fluid—exposed them in the dry state, but made liquid by fusion; and to his great delight he found, as he had expected, that the process of decomposition proceeded, the oxygen appearing at the positive wire, while globules of a metallic substance were found at the negative one. The glory of having made the greatest discovery of the age was plainly DAVY'S. His praise would have been the same if, instead of at once discovering the alkalis to be oxides, and the metals forming the bases to be lighter than water, while one of them burned unheated in the open air, he had only shown these salts to be oxides of well-known metals; but as his investigation had been crowned with the discovery of strange substances—metallic, and yet like no other metals—the admiration excited was still greater.

The investigation of DAVY was afterwards prosecuted by GAY-LUSSAC and THÉNARD, who, however, for some time still regarded the metal to be a compound of the alkali with hydrogen. BERZELIUS, on the contrary, repeating DAVY'S experiments, satisfied himself of the correctness of the theory of the latter chemist.

SOURCES.—In consequence of its intense affinity for oxygen, potassium is never met with in nature uncombined. It occurs principally as carbonate of the oxide or potassa in the ashes of land plants, and also as chloride in those of marine plants. In the mineral kingdom, it is found as sulphate, as well *per se*, as in combination with earths and water, and especially in alum and aluminosilicate. In polyhallite it is associated with the sulphates of lime and magnesia. As nitrate of potassa, or saltpetre, it is found in large quantities on the surface of the earth; as chloride, it exists sparingly in rock-salt, in sea-water, and in many salt springs, and other mineral waters. It is also an ingredient in several rocks, especially in felspar, leucite, apophyllite, and potassa tourmalin, in all of which it exists as silicate of potassa. Being always contained in plants, its salts are of course a most important ingredient in soils.

PREPARATION.—The expensive and troublesome method of DAVY, for the production of this metal, has long been abandoned, or at least is exhibited only as an interesting example of the power of electricity in producing chemical decomposition. The following process invented by GAY-LUSSAC and THÉNARD, and subsequently modified by BRUNNER, WÖHLER, and MITSCHERLICH, is that most frequently adopted. The salt made use of is the carbonate of potassa, and by careful manipulation, large quantities of metal may be obtained. The reducing agent employed is charcoal in a state of the most minute division. These ingredients are most readily procured in a proper admixture by the calcination of *argol*, or crude bitartrate of potassa. MITSCHERLICH directs six pounds of tartar to be ignited in a covered iron pot, till gases cease to be evolved. The product, termed *black flux*, is, while still hot, to be pulverized and mixed with ten ounces of coarsely-powdered charcoal. This addition is intended, by making the mass more porous, to allow of the more

easy escape of the gases subsequently developed. The whole is then transferred as quickly as possible to a wrought-iron quicksilver bottle, to the mouth of which an iron tube, not exceeding five inches in length, is screwed, to serve as a connection to a copper receiver, partly filled with rectified naphtha, and so constructed with partitions as to exclude the air. Another tube is inserted in this receiver, directly opposite to the tube in the bottle, so as, if necessary, by means of a strong steel rod, to cleanse the connecting tube, which occasionally becomes clogged by the products of decomposition. This tube serves also as an escape aperture for the gases. The whole arrangement is fixed in a wind furnace, as shown in Fig 421. This furnace should have a wide grate,

Fig. 421.

and a chimney ten feet high. The receiver is kept cool by means of ice applied to the outside. A strong and uniform heat, produced by the combustion of dry wood, is then applied to the bottle, and when the mass is sufficiently heated, the decomposition of the alkali by the charcoal begins, indicated by the appearance of a pink flame at the mouth of the tube. The potassium now distils over, accompanied by carbonic oxide and some solid products, and, dropping into the naphtha in the receiver, is effectually protected from the action of the air.

Instead of the iron bottle used in the above process, a gun barrel is sometimes employed, and is bent upwards at the thick end at a very obtuse angle, and downwards at the other end for about four inches, the middle part being laid horizontally in the furnace. This is the form of apparatus originally employed by GAY-LUSSAC and THÉNARD. The ingredients used by these chemists were hydrate of potassa, and metallic iron in the form of wire, filings, or borings. The latter were placed in the middle of the tube, and the potassa salt contained in the anterior bent portion of the tube was gradually fused and allowed to flow down; and coming in contact with the iron at a white heat was decomposed, yielding potassium and hydrogen

gas, which latter escaped by the lower end of the barrel, and the potassium was collected as previously described. To preserve the iron bottle or gun barrel used in these processes from wasting away rapidly by the action of the intense heat, it has been recommended to coat them externally with luting. GAY-LUSSAC and THÉNARD used for this purpose a mixture of one part of clay, five of fine sand, and a small quantity of horse dung; this luting is slowly dried, and the cracks filled up with fresh material. MANTELL incloses the gun barrel in a tube of baked clay, of such a width as to allow of the expansion of the barrel. SCHADLER and WERNER surround the bottle with a wire net, and on this the former applies a luting composed of two parts of pounded Hessian crucibles, one part of pipe-clay, and some cow hair; the latter two or three coatings of thin paste consisting of coarse quartz sand and a little clay. ANTHON covers the bottle with a mixture of loam and sand, and GALE with a mixture of equal parts of sand, clay, and soap-stone.

Instead of the mixture of charred tartar and charcoal, recommended by MITSCHERLICH, one of carbonate of potassa and charcoal in proper proportions may be used. KUKLA evaporates to dryness a mixture of three parts of pearlash dissolved in water, with the addition of one part of flour, carbonizes the residue, mixes it when cold with sufficient water to moisten it slightly, and transfers it to the bottle. It is always desirable to employ an excess of charcoal, as the rapid choking of the tube, as well as the fusion and projection of the contents of the bottle, is thus prevented. If a complete stoppage is actually formed in the tube, the greatest care must be exercised in reopening it; and if the attempt be successful, which is not always the case, masses of burning potassium may be forcibly projected by the sudden expansion of the compressed gas in the bottle, and occasion serious injury to the operator. The latter should therefore expose himself as little as possible, and his hands should be carefully protected by leathern gloves. The metal adhering to the borer should also be quickly scraped off into naphtha or rock oil, and should it take fire, extinguished by covering with a plate.

The theory of the production of potassium from the carbonate of potassa, by heating in contact with charcoal, is not clearly understood. In its simplest form, the decomposition may be represented thus— $K_2O, CO_2 + C_2 = K + 3CO$. Unfortunately, however, the greatest portion of the potassium at the moment of separation enters into combination with the carbonic oxide, forming a grey powder termed croconaceous matter, and from which, by digestion in water, *croconate* and *rhodizonate* of potassa may be separated. The grey powder is possessed of most powerfully explosive properties, and if the greatest care be not exercised in removing it from the tube and other parts of the apparatus—such as carefully excluding it from the atmosphere until quite cool, and soaking well in naphtha previous to attempting its removal—the most dangerous accidents may occur. The loss in potassium, owing to the formation of these compounds, is very great—amounting even under the most favourable circumstances to at least one half of the metal contained

in the mixture. PLEICHL obtained from six pounds of tartar, carbonized and mixed with six ounces of charcoal, nine and a quarter ounces of potassium, equal to 9.2 per cent. This is nearly one half of the total amount present, and may be considered a good yield. In most cases the product is much less.

PURIFICATION.—Potassium, as obtained in the processes above described, is found in the receiver in the form of globules mixed with carbonaceous matter. From this the visible globules are picked out with a pair of forceps, and by distilling the black residue a further quantity may be separated. The metal thus collected is, to separate remaining impurities, tied up in a linen bag and heated to about 150°, and then pressed out with a pair of wooden tongs. A far more effectual method of purification is, however, by distillation from a small iron retort, with which a short wide tube is connected, as represented in Fig.

Fig. 422.

422. This bottle is, after being filled with the crude metal, slowly raised to a strong red heat in a small air furnace. The potassium after some time begins

to pass over, and is received into naphtha. The process requires to be conducted with great caution, otherwise a dangerous explosion may ensue. Under any circumstances there is a considerable loss of metal from oxidation and other causes.

PROPERTIES.—Potassium is of a bluish, or silver-white color, and is possessed of a high degree of metallic lustre. Its consistence is very variable according to the temperature; below 32° it is brittle, and its fracture has a crystalline texture. At 60° it is malleable, and easily cut with a knife. At about 130° it enters into perfect fusion, and in appearance resembles mercury; and at a bright red heat it boils and rises in green vapor. Its specific gravity at 60° is 0.865; it is, therefore, lighter than water. When exposed to the air, potassium is instantly tarnished by the formation of a film of oxide; indeed so powerful is its affinity for oxygen, that when thrown on the surface of water, it instantly takes fire, forming potassa and liberating hydrogen gas. Potassium must always, therefore, be kept in naphtha, rock oil, or some liquid free from oxygen. The brilliant lustre of this metal is most beautifully shown by heating it in melted tallow, or by pressing a small portion between two plates of glass. The symbol for potassium is K, and its equivalent 39. Owing to its intense affinity for oxygen and the other metalloids, potassium is a most powerful instrument of research; thus, it decomposes all oxides, in most cases with complete reduction; and, with the aid of heat, all carbonates, phosphates, sulphites, sulphates, nitrates, and many other salts, withdrawing the oxygen not only from the acid, but also from the base. By its means many metals, previously unknown in the separate state, have been withdrawn from their combinations, and may now be prepared in any quantities to supply the demand for them in the arts and manufactures. Potassium has also been employed in surgery, as a substitute for the

actual cautery; in some cases with most beneficial results.

OXIDES OF POTASSIUM.—By combining with oxygen, this metal forms three compounds—suboxide, K_2O ; protoxide, KO ; and peroxide, KO_2 . The first named is produced when potassium is heated with a limited supply of air in a close vessel, or when it is heated with the higher oxides. The protoxide is obtained when an equivalent of potassium is allowed to act upon one of water, in a vessel from which the air is carefully excluded.

The decomposition is as follows:—

It is also procured by exposing the peroxide to a strong heat. The latter—the highest oxide—is produced when the metal is burned with free access of air or oxygen gas, by burning the suboxide and the protoxide, and also by the continued ignition of the nitrate of potassa. None of these oxides, *per se*, are of use in the arts or manufactures, and therefore will not require further mention. The protoxide, however, in combination with water, is a most important salt, and demands a more detailed notice.

HYDRATE OF POTASSA—Caustic Potassa.—This salt is most conveniently prepared by decomposing carbonate of potassa by hydrate of lime. One part of the carbonate is heated with twelve parts of water till the solution boils; slaked lime—prepared by mixing three parts of warm water with a little less than one of burned lime, and keeping it in a covered pan till the latter is reduced to a soft powder—is gradually added with constant agitation. The vessel is then covered, and its contents boiled for a quarter of an hour. The caustic solution is now tested by decanting a small portion and pouring it into hydrochloric acid; if there be no effervescence, the potassa is completely decomposed; in the contrary case, longer boiling, perhaps with the addition of more lime, is requisite. When a portion of the liquid no longer disengages carbonic acid on the addition of a stronger one, the whole is allowed to remain at rest for some time, in order that the carbonate and the excess of hydrate of lime may subside. The clear liquor is then siphoned off, concentrated by evaporation in covered iron pots, and, should it become turbid, set aside for some time and then again decanted. Lastly, the solution is rapidly boiled down in a polished iron or silver vessel till it acquires the consistence of oil, and on cooling concretes into hard masses. Carbonate of potassa is also decomposed by lime at ordinary temperatures; but in this case the decomposition is effected less rapidly, and the carbonate of lime formed being much less dense than when ebullition is used, its separation is much more difficult. As thus prepared, this hydrate frequently contains considerable quantities of alumina, silica, and phosphoric acid.

For use in the laboratory, hydrate of potassa, prepared as above, is treated with rectified spirit of wine in a stoppered bottle. The solution is allowed to deposit, decanted and evaporated in a silver dish, until fumes cease to be evolved, adding from time to time during the evaporation some water to prevent blacken-

ing of the mass. Except a minute trace of alumina, this hydrate, if carefully manufactured, is free from other impurities.

To obtain it perfectly free from alumina, SCHUBERT directs hydrate of potassa to be prepared by decomposing the sulphate of that base by means of hydrate of baryta. A solution of this latter salt is added to one of pure sulphate of potassa in exactly sufficient quantity to effect decomposition. The decanted solution is then evaporated as previously described.

A still better method for the production of this salt in a state of chemical purity is the following, recommended by WÖHLER. Put one part of nitrate of potassa, and two or three parts of sheet copper cuttings, in an iron or copper crucible in alternate layers; cover the latter, and expose it for half an hour to a moderate red heat. Allow the mass to cool, treat it with water, let the solution deposit in a tall cylinder, and afterwards remove it by means of a siphon. By evaporation the perfectly pure hydrate may then be obtained.

According to FUCHS, hydrate of potassa may be economically obtained from certain varieties of felspar and from mica. For this purpose the minerals are calcined with lime, then left for some time in contact with water, and the solution is afterwards filtered and evaporated. From his statement it appears that nineteen per cent. of potassa may be obtained from felspar, and fifteen per cent. from mica.

Hydrate of potassa is a white opaque mass, which, when broken, exhibits a crystalline fracture. Its specific gravity is 1.7. It fuses at a low-red heat, and at a white heat volatilizes unaltered. Its taste is acrid and corrosive. It has a strongly alkaline reaction, a rapid solvent action on animal matters, and is the most powerful base known. Its formula is KO, HO ; it is very deliquescent, very soluble in water, and crystallizable. The following table, deduced from DALTON's experiments, shows the quantity of anhydrous potassa contained in solutions of various densities:—

Specific gravity.	Potassa per cent.	Boiling point. Degrees.
1.68	51.2	329
1.60	46.7	290
1.52	42.9	276
1.47	39.6	265
1.44	36.8	255
1.42	34.4	246
1.39	32.4	240
1.36	29.4	234
1.33	26.3	229
1.28	23.4	224
1.23	19.5	220
1.19	16.2	218
1.15	13.0	215
1.11	9.5	214
1.06	4.7	213

The latter is about the strength of the solution of potassa of the London Pharmacopoeia.

The impurities most frequently met with in solution of and solid hydrate of potassa are carbonate of lime, oxide of iron, silica, alumina, carbonate and sulphate of potassa, and chloride of potassium. Carbonic acid is indicated by effervescence on the addition of an acid. Carbonate of lime and oxide of iron remain insoluble when the salt is treated with water. Silicic acid and

alumina are precipitated when an acid is gradually added to saturation, and the latter is redissolved by a slight excess of acid. The presence of a sulphate is shown by the addition of nitrate of baryta to a solution previously acidulated with nitric acid, and of chloride of potassium, by adding nitrate of silver to a portion of the same solution.

Hydrate of potassa is a most valuable agent to the chemist, and especially in the estimation of the carbon of organic bodies. It is also used to displace metallic oxides from their combinations, as a solvent for oxides of zinc and alumina, also for the decomposition of silicious minerals by fusion, for drying certain gases, and a variety of other purposes. In surgery, it is used in the solid state, cast into sticks, as a most powerful caustic. In medicine, its solution is also frequently employed, especially as an antacid.

Physiological Effects.—In the solid state its local action is remarkably energetic, rapidly destroying the tissue with which it comes in contact. When dissolved it is also powerfully corrosive, and consequently an energetic poison in large doses. It excites no constitutional action, except what depends on the local injury it occasions. In medicinal doses it possesses antacid and antilithic properties, and is administered in some bitter infusion.

CARBONATE OF POTASSA—*Potashes, Pearlash, Salt of Tartar.*—This salt is most readily obtained in a state of purity by heating the crystallized bicarbonate to a temperature exactly sufficient to expel its water and half of its carbonic acid, which is effected below a red heat. The residue dissolved in water and filtered yields the pure salt by evaporation. The solution in water and filtration is for the purpose of separating a small quantity of silica usually contained in the bicarbonate, and which is rendered insoluble by heating. If, however, the salt is heated too strongly, a silicate of potassa is formed, which dissolves with the carbonate; while, on the other hand, if not sufficiently heated, the residue still contains soluble silica. The pure salt may also be obtained by heating the bitartrate of potassa, or a mixture of nitrate and bitartrate to redness, lixiviating the residue, and evaporating to dryness; also, by passing carbonic acid into solution of potassa till saturated, evaporating to dryness, and exposing the mass to a dull red heat.

Properties.—Carbonate of potassa— KO, CO_2 —is very soluble in water, and the solution, when concentrated to about 1·2 and suffered to cool, deposits crystals containing two equivalents of water, and therefore having the formula $\text{KO}, \text{CO}_2, 2 \text{HO}$. As usually met with, it forms a white solid anhydrous mass, deliquescent, and at a red heat fusible without alteration. Its solution has a powerfully alkaline reaction and taste, but is only slightly caustic. It rapidly abstracts water from the atmosphere, and yields a dense solution originally termed *oil of tartar per deliquium*. The specific gravity of the pure anhydrous salt is 2·24. It is insoluble in absolute alcohol. Boiling water, on the contrary, dissolves more than its own weight of this salt. A cold saturated solution contains about forty-eight per cent., and its density is about 1·5. The subjoined table by TUNNERMANN shows the quantity of anhy-

drous salt contained in solutions of the densities enumerated:—

Specific gravity.	Per cent.	Specific gravity.	Per cent.
1·4812	40·504	1·2282	19·580

The carbonate of potassa of commerce—usually termed *potashes* or *pearlash*—is an article of great importance in the arts and manufactures; and it is, therefore, necessary to dwell at some length on its production, the methods for procuring it on the large scale, and its purification for manufacturing purposes. As previously mentioned, potassa is an essential ingredient in plants, and it is from this source that the carbonate is obtained for commercial purposes; for though some other salts of this base are frequently met with in nature and in large quantities, still potashes are never procured on the large scale by a chemical decomposition of these salts. The great natural depositary of potassa is the felspar of granite and other unstratified rocks, where it exists in combination with silica, and quite insoluble in water. Its extraction directly from this source, though it has been attempted on the large scale, is attended by difficulties so great as probably never to allow its successful prosecution. As the rocks disintegrate into soils, however, the alkali acquires solubility; and, being taken up by plants, it accumulates in their substance in a condition highly favorable to its subsequent applications. The precise condition in which potassa is contained in the vegetal kingdom, is to a great extent involved in mystery; and the same may be said, also, as to the part it plays in the organism of plants. A considerable portion, however, undoubtedly exists in combination with vegetal acids—as tartaric, citric, malic, and oxalic—and in smaller quantities in some plants as carbonate. Besides potassa, however, all vegetables contain other inorganic constituents in variable proportion—as, for instance, chlorides of potassium and sodium, sulphates of potassa and soda, carbonates and phosphates of lime and magnesia, silicate of alumina, some metallic oxides, as those of manganese, iron, and copper, and also nitric acid, iodine, and bromine, in combination with oxides and metals. The alkalies, potassa and soda, appear to be capable of replacing each other in the constitution of plants, as it is found that in those growing on the shores of the ocean, where the latter base is of course more abundant, it usually predominates; while in plants produced on an inland soil, potassa is always prepon-

derant; indeed, according to CHAPTAL and FONTENELLE, the same plants which, when cultivated at a short distance from the sea, yield soda salts, when reared at a distance of ten leagues produce salts of potassa. Other researches which have been made upon this subject leave no doubt that plants, in the absence of a particular ingredient in a soil, can take up some other, which, as regards chemical action, is endowed with similar properties, and that bases replace each other and act conjointly with reference to the functions of plants. This property of plants to secrete other principles than those generally supposed to be essential to their growth, and which appear to be their natural sustenance, is very remarkable; it is, nevertheless, of frequent occurrence—indeed, the ashes of two specimens of the same species of plants are seldom perfectly alike in composition, and are often considerably at variance. Thus, SAUSSURE found in the ash of a fir the following ingredients:—

	Per centage
Carbonate of potassa,	3.6
“ lime,	46.34
“ magnesia,	6.77

In the ash of the same tree, but grown in another locality, he found of—

	Per centage.
Carbonate of potassa,	7.36
“ lime,	51.19
“ magnesia,	0.00

In both cases the proportion of oxygen in the base of the salts is precisely the same—namely, 9.0. It appears, therefore, that the action of a base is dependent upon the amount of oxygen it contains, and is, indeed, measured by that quantity; the bases of such ashes—independent of that portion which is in combination with mineral acids—must together contain one and the same quantity of oxygen. This view is confirmed by the experiments of WILL and FRESSENIUS, who obtained from the ashes of tobacco very variable results as to the proportion of the different ingredients; but as regards the oxygen of the base, the total amount in one case was 24.27, and in the other 24.57. The nature of the ash also, as proved by SAUSSURE, varies in the same specimen with the part of the plant from which it is obtained, and, even in the same part is not uniform throughout the different periods of development and changes of season.

The first operation in the production of potassa is the combustion of the wood, when, after the volatilization of the destructible matters—as carbon, hydrogen, *et cetera*—all the mineral constituents abstracted from the soil naturally remain in a fixed state. This residue may contain all, or only a portion of, the constituents previously mentioned as the mineral food of plants. The bases—potassa and soda—are found for the most part as carbonates, formed during incineration from the decomposition of the vegetal acids with which they were combined. In general, the herbaceous plants yield much more ash than shrubs, and these again more than trees. In the latter the bark and leaves afford the largest quantity, next the branches and twigs, while in the trunk only a very small quantity is contained. The subjoined table shows the centesimal

amount of ash obtained from the plants mentioned, together with the name of the authority:—

The proportion of carbonate of potassa contained in the ashes of wood is also very variable, and it is always associated with a greater or less quantity of carbonate of soda. Other soluble salts are sulphates and silicates of these alkalies, and chlorides of the metals. If the ash is treated with water, these salts are separated, whilst carbonates, phosphates, and silicates of the alkaline earths remain insoluble. The value of a particular ash is, therefore, determined by the estimation of the relative proportion of its soluble and insoluble

constituents. In the appended table are given the experiences of BERTHIER and others on this point:—

Ashes.	Soluble.	Insoluble.	Authority.
White beech wood,	19-22	80-78	Berthier.
White beech charcoal,	18-00	82-08	"
Red beech wood,	16-30	83-70	"

Extraction of Potashes.—The American process for the extraction of potashes is thus described by MORFIT. The incineration of the plant is effected in dry pits, sunk into the ground to a depth of three or four feet. The plant is thrown in in portions, and burned until the pit is nearly full of ashes. The latter are then removed, mixed with about five per cent. of lime, and drenched with successive portions of fresh water. The ash-tubs or vats employed in this operation are usually formed from tar-barrels, by cutting them in half. A number of these are furnished with two cross-beams, upon which rests a false cullendered bottom covered with straw, and below this is a cock for the removal of the lie. The first liquor running through being saturated is passed at once to the evaporating pan; while the second or third runnings, being weaker, are reserved and poured upon fresh ash until completely saturated. The evaporating pans are broad and shallow, and made of iron with corrugated bottoms, to produce greater extent of heating surface; and as evaporation progresses, new supplies of strong liquor are poured in, and the heat is continued until a sirupy consistence is attained, when the fire is gradually slackened, and the contents of the pan, becoming solid, are dug out and placed aside as *crude potashes*. By subjecting this mass to the heat of a reverberatory furnace, most of the sulphur, and all excessive water and empyreumatic matters are expelled, causing a loss of ten to fifteen per cent. This modified product is white, with a bluish tinge, contains more carbonic acid than the original crude product, and takes the name of *pearlash*.

The process employed in Russia and Northern Europe is the same in principle as that above described, and is conducted in a similar manner, except that no lime is used in the lixiviation process. The difficulty experienced in the removal of the potashes from the evaporating pans may be avoided, in a great measure, by constant agitation of the lie while cooling. The salt thus obtained, however, contains twice as much water as in the ordinary method. By some producers a separation of the greater part of the difficultly soluble

sulphate of potassa—a salt largely consumed by the manufacturers of alum—is effected by evaporation and cooling from the lie, which has been saturated with the soluble constituents of the ash, and a much superior variety of potashes is obtained.

The insoluble portion of the ashes of plants, and which remains in the lixiviating vat, is employed in glasshouses for the production of green bottle-glass, and, on account of the phosphates it contains, is also valuable as a manure.

The production of potashes is principally carried on in those countries where, being thinly populated, wood is very abundant. In Russia, straw and weeds are burnt for the potassa they contain; and in some districts of France, yeast, the lees of wine, and distillery refuse are also applied to the same purpose; while in Java, potashes are extracted from the stems and leaves of the indigo plant, after the separation of the coloring matter.

The principal varieties of potashes met with in commerce are American, Russian, German, Saxon, and Dantzic. They vary but little in appearance, and derive their names from the locality whence they are imported. The proportion of carbonate of potassa contained in the crude ashes varies from forty to eighty per cent., and the residue for the most part consists of sulphate and silicate of potassa and chloride of potassium. According to the analysis of VAUQUELIN, American potashes contain of pure hydrated potassa—either in the free state, or combined with carbonic acid—74 per cent., Russian potashes 67, and American pearlashes 65·5 per cent. Various European specimens, also examined by this chemist, yielded from 38·5 to 62 per cent.

Valuation of Potashes—Alkalimetry.—The commercial value of potashes depends entirely upon the proportional amount of carbonate or caustic alkali contained in them; and it is, therefore, important to be able to effect the estimation of these salts otherwise than by a complete chemical analysis, as the tediousness of the operation, the great practice required in manipulation, and the cost of apparatus, render any such method nearly impracticable to the manufacturer. Several processes have been devised to ascertain the amount of available alkali in the crude product with sufficient accuracy for the purposes of commerce. Amongst these, the one most frequently adopted is that first broached by RICHTER, afterwards practised by DESCROIZELLES, and subsequently improved by GAY-LUSSAC. It consists in determining the quantity of an acid required to neutralize the alkaline reaction of a known weight of the salt to be examined, which, of course, represents the amount of available alkali present. Sulphuric acid is generally employed for this purpose; for while it wholly expels the carbonic acid, and combines with the whole of the free alkali, it does not extend its decomposing influence to the foreign salts in any important degree. The measure used in this process, termed an *alkalimeter*, is shown in Fig. 422. The cylinder is usually about twelve inches in height, and three-fifths of an inch internal diameter, and is graduated uniformly downwards into one hundred divisions.

For estimating the value of potashes, the following is the most convenient method. A quantity of sulphuric acid is taken and gradually added to about nine times its bulk of water, and the mixture is allowed to cool; 112.75 grains of perfectly pure anhydrous carbonate of soda are then taken and dissolved in about a half-pint of water, and the solution is heated. The

Fig. 422.

alkalimeter is now filled to exactly one hundred measures with the mixture of acid and water, and the latter is gradually poured into the soda solution to complete saturation. The number of measures of acid used is then carefully read off, and these are exactly equivalent to one hundred grains of pure potassa. If, therefore, eighty measures of acid are required, by adding to every eighty measures remaining twenty additional measures of water, an acid is obtained of which one hundred alkalimeter measures exactly represent one hundred grains of potassa—that is, one grain to each measure. If a greater or less quantity of acid is required for the saturation of the carbonate of soda, the quantity of water required to be added to the acid is diminished or increased according to such proportion, so that one hundred measures of the acid liquid shall contain exactly the quantity of the stronger acid used to effect the neutralization of the soda salt.

All that is now required, in order to ascertain the quantity of real potassa in any sample of potashes or pearlash, is to dissolve one hundred grains of the sample in warm water, filter, to remove all insoluble matters, and add the dilute acid in small successive portions, until, by the test of litmus paper, the solution is exactly neutralized. Each division of the acid added indicates one grain of pure potassa.

With regard to the performance of the operation, it is necessary to exercise great care to hit the exact point of saturation of the alkali. With caustic alkali this may be effected with ease; but in the case of the salt under discussion, the liberated carbonic acid, which imparts a red tint to the litmus paper, causes some difficulty. The first addition of the acid, however, does not produce effervescence, because the carbonic acid expelled, instead of escaping, combines with the carbonate as yet undecomposed, converting it into bicarbonate; but as soon as half the quantity of potassa contained in the solution is saturated, effervescence ensues, and the solution containing free carbonic acid now changes the blue color of litmus to purple or bluish-red. On the addition of more acid, with constant stirring of the solution, and with increased caution as the point of neutralization is approached, which is known by repeatedly testing with the litmus, until only one drop is added at a time, when the alkali is exactly saturated, the slightest excess of acid produces a permanently red stain after drying. The alkalimeter is then allowed to rest for a short time, in order that the liquid may drain from the sides, and the number of divisions of acid employed is carefully read off, and the per centage amount of potassa contained in the salt examined is at

once ascertained, being equivalent to the number of measures of acid used.

A modification of the above alkalimetric process has lately been proposed by MOHR which gives good results. Instead of sulphuric acid, he employs crystallized oxalic acid. The great disadvantage of this method is, that besides the solution of acid, a standard solution of soda is required as a counter test. In his process the alkali to be examined is dissolved in water, and the solution colored blue with tincture of litmus. As much of the test acid is then added as will suffice to impart a violet color to the fluid. The latter is then boiled, and receives a further addition of acid until the color is decidedly yellowish-red. The alkali is lastly oversaturated with acid, and the last traces of carbonic acid are removed by boiling, *et cetera*. The excess of acid used is now ascertained by addition of the test solution of soda to exact neutralization, and deducting this from the whole quantity employed, the quantity of crystallized oxalic acid required for the saturation of the alkali is ascertained. Every sixty-three grains of this acid represent forty-eight grains of pure potassa.

In the laboratory of the chemist, indeed wherever the examination of alkaline solutions, besides those of potassa, is frequently practised, an acid is prepared that may be adjusted for all alkalies, that is, of such a strength that one thousand grains measure will exactly saturate a certain quantity of each base. The mode of effecting this object is as follows:—An alkalimeter is used of similar construction to that previously described. Into it are poured one thousand grains of water, and the space it occupies is accurately graduated into one hundred equal parts. Opposite to the numbers 23.44, 54.63, 58.96, and 65.0, lines are traced—the first of which is marked *soda*; the second, *carbonate of soda*; the third, *potassa*; and the fourth, *carbonate of potassa*. Dilute sulphuric acid is now prepared, of specific gravity 1.127 at 60°, and is made by adding to one measure of concentrated acid four measures of water. This standard acid is of such strength, that when poured into the tube till it reaches either of the four marks above-mentioned, the exact quantity is obtained for the neutralization of one hundred grains of the alkali, the name of which is written opposite to it. If water be now added until it reaches the beginning of the scale, each measure of the mixture will exactly neutralize one grain of the alkali named, and at once shows the centesimal amount of pure caustic or carbonate of alkali contained in the sample under examination. The strength of the acid is verified by the means previously described, and the process is conducted precisely in the manner directed in the estimation of the potassa salt.

The various kinds of alkali of commerce usually contain a greater or less proportion of chlorides and sulphates. The presence of these does not interfere in the slightest degree with the above methods of estimation. In some cases, however, sulphides, sulphites, and hyposulphites are also present, and these, neutralizing a certain quantity of the test acid, render the determinations more or less inaccurate. The first of these salts evolves sulphide of hydrogen, the second sulphurous acid, and the last hyposulphurous acid, which is immediately decomposed into sulphurous acid

and sulphur. On the addition of an acid, therefore, to a portion of the salt under examination, the presence of sulphite or hyposulphite is indicated by the intensely penetrating nature of the sulphurous vapor eliminated, while a sulphide is shown to be present by the blackening of a slip of paper moistened with acetate of lead and a little ammonia, and placed in contact with the evolved gas. A single experiment serves for the detection of both gases, as it has been lately shown, though previously disputed, that the two may be simultaneously evolved. Should the salts of these acids be proved to be present, the error they would introduce is easily obviated by the addition of a little neutral chromate of potassa, the acid of which immediately transforms the sulphites, hyposulphites, and sulphides into sulphates, with separation of water and sulphur.

An alkalimetric process, varying in principle from those above described, has been devised by FRESenius and WILL, and consists in ascertaining the amount of carbonic acid contained in the sample to be examined, and which is displaced on the addition of an acid. As in the preceding processes, any insoluble matters must be separated by treatment with water and filtration, and if, besides carbonate, caustic alkali is also present, this must be converted into carbonate as follows:—The solution of the weighed portion of the sample after filtration is evaporated nearly to dryness, and solution of carbonate of ammonia is added in excess; the evaporation is then continued, and the residue is finally dried at a high temperature, so as to expel all traces of undecomposed carbonate of ammonia. This salt yielding its carbonic acid to the more powerful base, converts the whole of the latter existing as caustic into carbonate of the alkali. The dry residue is then transferred to an apparatus—Fig. 423—carefully rinsing the dish, and adding the washings to the salt. The rest of the

was made in 1752 by CARTHEUSER. He directs it to be prepared by adding to a solution of the neutral carbonate of potassa as much carbonate of ammonia as will yield to the potassa salt a quantity of carbonic acid equal to that already present. The proportions employed by DUFLOS are four parts of carbonate of potassa, four of water, and one of carbonate of ammonia. The operation is conducted in a retort, that the evolved ammonia may be collected. After boiling for an hour, the solution is left to cool, when a separation of crystals of bicarbonate ensues. These are removed, and to the mother-liquid is added an equal quantity of the ammoniacal salt, and the process is continued as before. Bicarbonate of potassa is also produced when a solution of neutral carbonate is saturated with carbonic acid, and this process is the one usually employed. The carbonic acid gas eliminated during the fermentation of saccharine solutions is frequently applied to the production of this salt, or it may be liberated from marble or chalk by means of dilute sulphuric or hydrochloric acid. Before coming in contact with the potassa solution, the gas is conducted through a bottle half filled with water, to wash away any impurities that may be mechanically carried over. When the solution no longer absorbs carbonic acid it is set aside, to allow the deposition of crystals, of which a further quantity may be obtained by concentration of the mother-liquid, and a further addition of carbonic acid.

Properties.—Bicarbonate of potassa, in the crystalline condition, has the form of an oblique rhombic prism, and is combined with an equivalent of water. Its formula is $\text{KO}, 2 \text{CO}_2, \text{HO}$. It is unalterable in the air, but when strongly heated loses half its acid and the whole of the water, reverting to the state of neutral carbonate. When heated in water, also, it is partially decomposed, and, by long boiling, completely, with production of neutral carbonate. The taste and reaction of bicarbonate of potassa is slightly alkaline. It dissolves in four parts of water at 60° , and in little more than its own weight of this liquid at a boiling heat. In alcohol it is nearly insoluble. It is occasionally employed in the preparation of pure neutral carbonate of potassa.

Physiological Effects.—This salt, as well as the preceding, is possessed of antacid properties. It is, however, much less corrosive than the neutral carbonate. Like this latter salt, it has also diuretic and antilithic properties; and being less unpleasant to the taste, as well as less irritating, it may be administered in much larger doses. It is frequently used also for producing effervescing powders.

SULPHATE OF POTASSA—Vitriolated Tartar, Salpolycrest.—This salt is most conveniently prepared by neutralizing with carbonate of potassa the bisulphate of this base, as obtained in the preparation of nitric acid, or by expelling the excess of sulphuric acid by heating the bisulphate to redness. It may also be formed synthetically by saturating carbonate of potassa with diluted sulphuric acid, and evaporating the liquor that crystals may be formed. Sulphate of potassa— KO, SO_3 —is especially distinguished by its hardness. The form of the crystal is that of a six-sided prism. These crystals contain no water of combination; but when heated,

Fig. 423.

operation is conducted precisely as described in the estimation of manganese ore—omitting the oxalate of potassa. Every twenty-two grains loss of weight in the apparatus represents forty-seven of potassa, or thirty-one of soda, according to the salt under examination.

Bicarbonate of Potassa.—The discovery of this salt

decrepitate, owing to the volatilization of a small portion of this liquid mechanically held. Exposed to red heat, sulphate of potassa fuses, but without decomposition, and at a white heat, volatilizes. The taste of this salt is bitter, and feebly saline. It dissolves in about eleven parts of water at 60°, and four at 212°. In alcohol, and in solution of potassa, it is quite insoluble. It is principally employed in the production of alum and saltpetre. Both sulphate and bisulphate of potassa are also used in medicine as gentle laxatives, and the latter salt occasionally to replace the vegetal acids in the preparation of effervescing draughts.

NITRATE OF POTASSA—Saltpetre.—This important salt is found abundantly as a natural product, usually associated with the nitrates of lime, magnesia, *et cetera*. It is obtained in a state of purity by decomposing carbonate of potassa by nitric acid. The solution by evaporation deposits crystals of the pure salt. It may be obtained also from the saltpetre of commerce, by pounding the latter, moistening it with one-sixteenth of its weight of nitric acid and a small quantity of water, evaporating the liquid to dryness with constant stirring, and repeating the process if the salt still contains chlorine.

Properties.—Nitrate of potassa— KO, NO_3 —is dimorphous. Its ordinary form belongs to the right prismatic system. More rarely, the crystals are obtuse, flattened rhombohedrons. Under both conditions it contains no combined water, but its crystals are never quite free from water lodged mechanically within them; and hence, on heating, decrepitation ensues. The taste of this salt is saline, accompanied with a sense of coolness. It is soluble in seven parts of water at 60°, and in an equal weight at 212°. At 616° it undergoes the igneous fusion, and at a strong red heat is completely decomposed with evolution of oxygen and nitrogen gases, leaving a mixture of potassa and peroxide of potassium. When mixed with combustible matter and heated, or when thrown in a state of fusion on some of the metals, rapid oxidation takes place at the expense of the oxygen of the nitric acid.

The saltpetre of commerce is derived principally from the East Indies, where, as also in Persia, Egypt, and Spain, it appears as an efflorescence on the surface of the soil. In some other countries, as the coast of the Adriatic, in Ceylon, North America, Africa, and Teneriffe, it is found on the walls of natural caverns formed in limestone rocks, and which contain also felspar and magnesia. It is also found widely distributed in some parts of Hungary, but in no case extending to any great depth below the surface of the ground, nor even to such a depth as the air cannot penetrate. Its appearance on the surface of the ground is explained by its ready solubility in water, as when its solution, in obedience to the law of capillary attraction, rises to the surface, the liquid is vaporized by the action of sun and air, and its place is immediately occupied by a fresh portion from below, which disappears in the same manner, until at last an incrustation of the salt is formed of considerable thickness, either in solid crystals, or as an effloresced mass.

Exudations containing saltpetre are not unfrequently met with upon new walls, and also, under certain cir-

cumstances, on old walls. Thus, in densely-populated towns, where the excrements of beasts of burden, refuse from slaughter-houses and from other trades of a similar kind, the water from the houses, the refuse of markets, *et cetera*, mix with the fluid in the drains, and are in a constant state of putrefaction—the coating of mortar on external walls, and especially near the base, gradually becomes covered with a white crystalline efflorescence, and the phenomenon is known as saltpetre rot. Indeed, whenever either accidentally or purposely a strong base, as lime, magnesia, or potassa, comes in contact with decaying vegetal or animal nitrogenous matters in presence of moisture, nitric acid is always generated, and, combining with the bases, produces nitrates; and these by contact with a potassa salt readily yield nitrate of potassa. The principle was, indeed, formerly extensively applied to the production of this salt.

Formation of Saltpetre—Nitrification.—Concerning the production of saltpetre, various theories have been from time to time promulgated, each of which has had large numbers of supporters, eminent for extensive chemical knowledge. GLAUBER, and subsequently STAHL, occupied themselves with this subject. About a century after the investigations of the latter chemist, LAVOISIER published a theory of the process; and since then, amongst others, KUHLMANN, THOUVENEL, THÉNARD, LONGCHAMP, GAY-LUSSAC, and LIEBIG, have devoted a considerable share of attention to the subject. The whole explanation of the process hinges upon the source of the elements of the nitric acid, and more especially upon the source of the nitrogen. The theory first published by LONGCHAMP supposes direct union of the nitrogen and oxygen of the atmosphere to be induced by electricity; and the nitric acid thus produced being brought to the ground in rain, combines with potassa and other bases capable of being converted into saltpetre by the action upon them of potassa salts. In reply to this, it may be observed that although, as first observed by CAVENDISH, lightning, in passing through the air, certainly induces combination of the elements of nitric acid, still this action is so limited, and of such rare occurrence, that its adoption as an explanation of the formation of saltpetre is quite inadmissible. LONGCHAMP, subsequently convinced of the untenability of his theory, adopted another one, in which he was supported by Dr. JOHN DAVY, PROUST, and others. This latter ascribes the union of the two elements to an action excited by the porous mineral constituents of the soil, similar to that of platinum black. The advocates of this view cite in defence of it the following experiments:—When earth forming nitre is freed from all its soluble salts by lixiviation, and is then exposed for several years to the action of the air, it yields a second crop of nitre, and these crops may be obtained three or four times in succession, although in different proportions. The supporters of this theory, supposing that all bodies containing nitrogen are removed by the first lixiviation, contend, therefore, that the nitrogen of the nitric acid subsequently produced, must have been derived from the air. That this conclusion is not justified by the circumstances of the case, was shown by GAY-LUSSAC, who, having estimated the amount of substances containing nitro-

gen, and compared this with the quantity of nitric acid actually generated, found that the proportion of the latter always corresponded with the quantity of nitrogenous matter present in the mixture, and that the yield of saltpetre was increased or diminished by an augmentation or decrease in the quantity of nitrogenized matters added. The conclusion that nitric acid is formed in such a case at the expense of atmospheric nitrogen, is, therefore, not in any way confirmed; indeed all experiments on the subject completely contradict the assertion that nitric acid may be generated in mixtures of earth destitute of nitrogenous matter. Considering, however, that nitrogenized organic bodies receive their nitrogen from the atmosphere in the form of ammonia, the primary origin of the nitric acid of saltpetre must be the ammonia of the atmosphere; and, in addition, it may be affirmed that ammonia is not only the ultimate source, but that it is also the immediate source of nitric acid; and hence the production of the latter may be expected wherever the ammonia and the conditions for its oxidation are found united. The truth of this theory is confirmed by the experiments of MARTIGNY, who found ammonia which had been confined with air over milk of lime, converted after six months into nitric acid; by those of KUHLMANN, who obtained a large quantity of nitric acid where a mixture of sulphate of ammonia, sulphuric acid, and bichromate of potassa, peroxide of manganese, or lead, were heated together; and by DUMAS, who has shown that when a current of moist air, mixed with ammonia, is passed over chalk moistened with a solution of potassa, at a temperature of 212°, there is formed after some time a considerable quantity of nitrate of potassa.

If, therefore, nitric acid is derived directly from the oxidation of the ammonia of putrefying organic matters, it appears probable that wherever the necessary bases are present in admixture, for fixing the acid, there saltpetre would be found. But, as in many other cases of decomposition, all the necessary conditions for the exertion of chemical affinities may be prepared, and yet the action will not ensue unless some impulse be given from without. This impulse proceeds most generally and energetically from some chemical action already in the course of operation. As has already been stated, the experimental conversion of ammonia into nitric acid has only succeeded at a high temperature or by the intervention of a free base, neither of which conditions frequently occurs in nature. The impulse which decomposing bodies can thus communicate, is, however, in all probability, sufficiently powerful to give rise to the formation of saltpetre at ordinary temperatures, and the time allowed for its production in nature very much exceeds the duration of ordinary experiments. It is highly probable that ammonia also plays a double part in the formation of saltpetre; first, in surrendering its elements to oxidation, and then also in saturating the acid, producing nitrate of ammonia. This salt then coming in contact with earthy and alkaline carbonates, decomposition ensues, nitrates of the earths or alkalis, and carbonate of ammonia being produced; thus $\text{NH}_4\text{O}, \text{NO}_5 + \text{MO}, \text{CO}_2 = \text{MO}, \text{NO}_5 + \text{NH}_4\text{O}, \text{CO}_2$. The ammonia therefore not only parts with its elements for the production of nitric acid, but also acts as a

carrier of the acid to a stronger base. The ammonia now become carbonate, and this salt possessing basic properties, it resumes its functions in a higher degree on account of the presence of moisture.

As already noticed, saltpetre is found in several countries, as a saline efflorescence on the surface of the earth. In India, the district of Tirhût is the most productive of this salt, and it is always more abundant in those parts containing a redundancy of carbonate of lime. An average sample of the soil analysed by STEVENSON, gave the following results:—

	Per centage.
Matter insoluble in acids,.....	50.0
Carbonate of lime,.....	44.3
Matter { Sulphate of soda,.....	2.7
soluble { Chloride of sodium,.....	1.4
in water, { Nitrate of lime,.....	0.9
{ Nitrate of potassa,.....	0.7
	100.0

The process for the extraction of the saltpetre is commenced by scraping off the surface from old mud heaps, mud buildings, waste grounds, *et cetera*, where the saltpetre has developed itself in a thin white efflorescence resembling frost rind. This saline earth being removed to the factories, is subjected to the process of lixiviation. This is effected in a large mud filter, lined on the inside with stiff clay. The filter has a false bottom of bamboo, covered with close-wrought grass mats, on which are placed vegetal ashes. Upon these the saline earth is laid. Water is then added to remove the soluble salts, and the solution thus obtained, filtering through the mats, drops into the empty space between the real and false bottom, and is conveyed away into an earthen receiver. In its passage through the wood ashes, the carbonate of potassa contained in the latter reacts upon the nitrate of lime, producing nitrate of potassa and carbonate of lime: thus $\text{CaO}, \text{NO}_5 + \text{KO}, \text{CO}_2 = \text{CaO}, \text{CO}_2 + \text{KO}, \text{NO}_5$. The solution is now evaporated in earthen pots, filtered, and put aside to crystallize. The impure salt thus obtained is termed *dhouah*. It contains from forty-five to seventy per cent. of nitrate of potassa. This is redissolved and recrystallized by the native merchants, and when thus purified is known by the natives as *kalmee*.—Stevenson.

In Ceylon the nitrous efflorescence on the walls of the natural caverns is detached, during six months of the year, with picks, together with a small portion of the rock, which latter, as it contains felspar, is doubtless the source of the potassa. The fragments are pounded, mixed with an equal portion of wood ashes, and water is poured upon the mixture. The earthy nitrates yield their acid to the potassa contained in the ashes, and the earths are precipitated as carbonates of lime and magnesia. The clear decanted lie, containing, besides the nitre of the rock, also that formed by the decomposition of the earthy nitrates, is evaporated in pits, exposed to the sun, and afterwards in pans by means of artificial heat. The crude saltpetre which crystallizes on cooling, is then fit for exportation.

During the period of the great war with France, at the end of the last and the commencement of the present century, the immense quantities of saltpetre, required for the manufacture of gunpowder, were produced in that country by an artificial process. The

great difficulty experienced by the government of that country, in obtaining the necessary supply of this indispensable material of warfare, induced them to offer a prize for the best treatise upon the principles of its production, and the best method of putting them in practice. The number of competitors was sixty-six. From the most valuable of these treatises, a process of manufacture was deduced, which, though tedious and costly, was perfectly successful, the execution of which was intrusted to BERTHOLLET, one of the most eminent chemists of that period, and who traversed the nation from one extremity to the other, giving instructions as to the mode of procedure. The process, of which the following is an outline, though no longer practised to any considerable extent, is of great importance. Animal refuse of all kinds is mixed with old mortar, or slaked lime and earth, and the mass placed in heaps, and protected from rain, is freely exposed to the air. From time to time these heaps are turned over and watered with fluids containing putrid nitrogenous matters, such as stale urine, cesspool liquors, or waters in which animal flesh or cheese has been soaked or washed. After a certain period a white mouldy appearance is observed on the surface of the heap, consisting of the nitrates of alumina, lime, magnesia, *et cetera*. When the process is at an end, the earth is said to be ripe, and is lixiviated with water in troughs in double bottoms, using only as much liquid as is necessary for the extraction of the salts. To the lie thus obtained, potashes, sulphate of potassa, or chloride of potassium is added in sufficient quantity to convert the nitrates of the earths into nitrate of potassa. If sulphate of potassa is used, milk of lime is also added to decompose the sulphate of magnesia that will be formed. After deposition of the heavy precipitate, the clear solution containing nitrate of potassa, chlorides of potassium and sodium, and a little sulphate of lime, is drawn or siphoned off, concentrated by boiling, and by repeated crystallization the salt is obtained comparatively pure.

Besides solid and liquid animal refuse, some vegetal substances are also applicable to the production of saltpetre. Thus, several weeds belonging to the families *solanaceæ*, *euphorbiacæ*, and *fungi*, pea, bean, and Indian corn straw, are especially valuable. In some countries, as for instance in Sweden, where saltpetre is one of the government taxes, vegetal matters are employed either with or without animal refuse. In the construction of the heap, the vegetal substance is first spread out upon a layer of earth; upon these the other solid matters are laid to a height of some feet, and the whole is covered with a second layer of earth. This heap is watered from time to time with urine, in quantity just sufficient to keep it moist throughout. During the summer, the heap, which has decayed to a uniform mass, is turned over once weekly, and in winter, once monthly, care being taken to keep the whole as loose as possible.

In Switzerland the earth below the flooring of stables, or in the neighborhood of dunghills, or in the cellars of dwelling-houses, where the remains of vegetal or other organic matters have been left to decompose, is the material used for the production of saltpetre. In Prussia a peculiar continuous process is practised. The

heaps are constructed with perpendicular sides; that opposed to the wind is simple and flat, while the opposite one forms a series of steps down to the bottom; on each step is a gutter, which carries back the excess of liquid poured upon it to a cistern. In this arrangement, the watering takes place at the back, while the evaporation proceeds principally at the sides exposed to the wind, so that the saltpetre is gradually drawn towards the latter part, whence it is removed, and an equal quantity of fresh earth is added behind. The great advantage of this method is that a heap is never totally destroyed, and the great difficulty experienced in the commencement of the process of nitrification is entirely removed. The preparation of saltpetre, by decomposing nitrate of soda, is pursued in some localities where potashes can be obtained at a low price. In this case the change is very simple, nitrate of potassa and carbonate of soda being produced. Thus, $\text{NaO}, \text{NO}_3 + \text{KO}, \text{CO}_3 = \text{NaO}, \text{CO}_3 + \text{KO}, \text{NO}_3$. All that appears difficult in this process is the removal of the carbonate of soda, but, as remarked by KNAPP, a greater difficulty arises from the presence of chloride of sodium in commercial nitrate of soda; for as soon as a little more potashes are added than correspond with the quantity of pure nitrate of soda, the excess decomposes chloride of sodium to no purpose; and in the opposite case the product is contaminated with portions of undecomposed nitrate of soda.

Purification.—The crude saltpetre as obtained by the above processes, as well as the rough salt imported from Ceylon and the East Indies, always contains more or less impurity, which may be organic, that is, vegetal or animal matter, or inorganic, as other alkaline and some earthy soluble salts, or both. The foreign matters most frequently present, and in the largest proportion, are the chlorides of potassium and sodium, in some cases exceeding twenty-five per cent. of the crude salt. These latter are of all impurities the most objectionable, and the most difficult to remove. The process of separation most frequently practised depends upon the fact that the solubility of nitre rapidly increases with elevation of temperature, while that of the two chlorides remains nearly constant. A roomy copper boiler is the one most frequently employed. A rough estimation of the amount of impurity present having been previously made, and the solubility of pure nitrate of potassa being known, namely, three parts to one of water, the crude salt is added to the boiling water, until as much nitrate of potassa is present as can be dissolved, the heat at the same time being increased until the saturated solution also enters into ebullition. The solution is now kept constantly stirred, and the scum which collects on the surface is removed. A large proportion of the chloride of sodium subsides, and is scooped out from the bottom of the pan. A further quantity of water is then gradually added, amounting to two-thirds of that originally employed, and afterwards an aqueous solution of common glue, containing one pound of the latter to every ton and a half of crude saltpetre operated upon, and the whole is again boiled and well agitated. The glue thus diffused through the liquid enters into combination with the organic extractive matter present,

and carries it to the surface in the form of scum, which is carefully removed; and after boiling for some time, the solution is perfectly clarified. The whole is then allowed to stand at rest for twelve hours, the heat being continued at about 190° , so as to prevent crystallization of the salt, which, if allowed, renders the after process much more tedious. The supernatant liquid is now carefully drawn off from the deposit of common salt and other matters into the crystallizing pan. This latter is a shallow copper vessel, the edge of which is firmly secured to a platform of oak. It is formed of two inclined planes, so arranged that the deepest point is at one of the narrow sides. As the liquor cools, the crystals quickly form, and if the liquor is left tranquil, they are of large size and clustered together. If, however, the liquid be constantly agitated while in the act of cooling, the salt separates in fine crystalline needles, termed *saltpetre flour*, and as it forms, is drawn out of the lie towards the top of one of the inclined planes of the pan, where it remains until the mother-liquor has drained from it. This method of crystallization, first recommended by BEAUMÉ and LAVOISIER, is far preferable to the old process in which the salt is allowed to separate from the tranquil liquid; as in this case, owing to the formation of larger crystals, and in clusters, a much greater proportion of mother-liquor is retained, and a second solution and crystallization is required to render the salt sufficiently pure for commercial purposes. The salt separated as above, when sufficiently dry, can contain only a very small quantity of mother-liquor, and consequently, also of the impurities therein contained. To effect the removal of the last traces of these, the crystalline mass is next washed in tubs provided with a false bottom drilled with holes. These tubs are filled completely with the salt, the latter being heaped up some inches above the rim. The washing-liquor is a saturated solution of *pure* nitrate of potassa, which, although it dissolves other salts that may be present as readily as would be the case with pure water, of course can have no effect upon the saltpetre. This liquor is poured upon the salt, so as thoroughly to wet the mass, and by means of a plug, is prevented from running off for a period of three hours, after which the plug is removed, and the salt well drained. This operation is again repeated, in this case with pure water, and these washings constitute the solution of nitrate of potassa which is employed for the first washing of a fresh portion of the salt. After being well drained, for which a period of some days is required, the saltpetre flour is dried with constant agitation in a pan economically heated by the flue of the boiler fire.

Refraction of Saltpetre.—A considerable proportion of the crude saltpetre of commerce always consists of foreign matters, and as its value is solely dependent upon the amount of pure nitrate of potassa which it contains, it is important to have some readily available means of ascertaining with accuracy the quantity of the pure salt, or, which answers the purpose equally well, the amount of impurities contained in a given sample. The determination of these impurities, or the loss which results from the purification or refining of saltpetre, is technically termed the *refraction*.

The foreign matters usually met with in crude saltpetre are chlorides of potassium, sodium, and magnesium, sulphates of potassa and lime, nitrate of soda, water, and traces of organic matter. The accurate quantitative analysis of such a mixture of salts is not a very easy problem; and yet their separation is essentially necessary, to render saltpetre available for the purpose to which it is almost wholly applied, namely, the production of gunpowder.

Several processes have from time to time been suggested for the refraction of saltpetre, many of which are however of little value, though even now extensively practised both in this and other countries. Whatever method be adopted, especial care must be exercised to procure a fair average sample of the salt to be examined.

The method of refraction principally employed in France, is that introduced by RIFFAUT, which, besides being very tedious, gives only approximate results. It consists in washing a weighed quantity of the dry crude salt, with a saturated aqueous solution of pure nitrate of potassa. This, although it cannot extract nitrate of potassa from the sample, effects the removal of all foreign soluble salts. When these are extracted, the salt remaining on the filter is dried and weighed, and the amount of loss sustained by the original sample is taken to represent the amount of impurity present. This method is liable to so many sources of error, as to render it quite inapplicable in cases where even a tolerable degree of accuracy is required. Under the most favorable circumstances, it indicates from one to three per cent. more nitrate of potassa than is actually present in the sample.

A better method is that suggested by GAY-LUSSAC, but which, as it requires great care and dexterity in its execution, is unfitted for practical use, except to the experienced chemist. In this process the nitrate of potassa is converted into carbonate by fusion with charcoal; and the quantity of potassa contained in the new salt is estimated exactly as directed when treating of the valuation of potashes, or ALKALIMETRY. Every forty-seven grains of potassa found, indicate one hundred and one grains of nitrate of potassa contained in the sample under examination.

Various other processes are practised by different analysts, in which the amount of nitrate of potassa contained in a given sample of crude saltpetre is deduced from the quantity of nitric acid present, and therefore they consist in the determination of this acid by any available means. Amongst them the method of GOSSART, as modified by PELOUZE, is the most frequently applied. This consists in the determination of the amount of protoxide of iron converted to the state of sesquioxide, by a weighed portion of the salt to be examined. The theory of this reaction is represented by the following equation— $6 \text{ Fe Cl} + \text{KO}, \text{NO}_5 + 4 \text{ H Cl} = 4 \text{ HO} + \text{K Cl} + \text{NO}_2 + 3 \text{ Fe}_2 \text{ Cl}_3$. That is to say, every one hundred and sixty-eight parts, or six equivalents of iron converted from the state of protochloride to that of sesquichloride, represent fifty-four parts, or one equivalent of nitric acid. The process is conducted as follows:—Thirty-one grains of pianoforte wire are dissolved in about fifteen hundred

grains measure of concentrated hydrochloric acid; to this is now added 18·7 grains of the saltpetre to be examined, and the flask containing the mixture is immediately closed and heated till the liquid boils. The latter quickly assumes a brown color, and the dense vapors of hydrochloric acid and nitric oxide which issue from the flask prevent the access of air, which, if allowed to come in contact with the mixture, by its action upon the nitric oxide, which it converts to nitrous acid, would oxidize a certain quantity of iron, and thus render the estimate of the nitrate of potassa apparently higher than it really is. When the solution has become of a clear yellow color, and perfectly transparent, the flask containing it is removed from the source of heat, and the liquid is transferred to a convenient vessel and diluted with two pints of water. A solution of permanganate of potassa of known strength is now cautiously added from a graduated burette, constantly agitating the mixture; and as soon as the latter acquires a faint rose-red tint, the addition of permanganate of potassa is discontinued, and the quantity employed to sesquioxidize the iron read off on the burette. The proportion of nitric acid contained in the sample is now readily deduced as follows:—Suppose the test solution of permanganate of potassa employed to be of such strength, that one hundred alkalimetric measures are required to sesquioxidize fifty grains of iron; and that fourteen divisions were required to complete the oxidation of the iron left in the state of protochloride after treatment with the saltpetre as above directed, the amount of protochloride corresponding to the fourteen divisions is at once found by a simple calculation—for if one hundred measures of the solution of permanganate are required to sesquioxidize fifty grains of iron, fourteen measures will suffice for seven grains. If this quantity be now subtracted from the thirty-one grains of iron originally employed, the remaining twenty-four grains represent the quantity sesquioxidized by the 18·7 grains of saltpetre employed. Now, as thirty-one grains of iron require 18·7 of pure nitrate of potassa to effect its complete oxidation, twenty-four grains of iron will require 14·48 of pure nitrate; this represents the amount contained in the 18·7 grains submitted to examination, and by the calculation, as $18\cdot7 : 14\cdot48 :: 100 : 77\cdot43$ = the per centage amount of pure nitrate of potassa contained in the sample.

In the process recommended by STEIN, the proportion of pure nitrate of potassa contained in a given sample of saltpetre is estimated by the amount of arsenious acid which it can convert to the state of arsenic acid. This method, though it gives accurate results, owing to the length of time required to perform the analysis, is inapplicable for ordinary commercial determinations, and will, therefore, not be further considered.

In the Editor's laboratory the method of refraction usually pursued is that recommended by ZENNER. The process for the determination of the nitric acid depends upon the ease with which the nitrates of the heavy metallic oxides are decomposed by heat. It is conducted as follows:—From ten to fifteen grains of the salt to be examined are introduced into a wide-bottomed porcelain crucible, and, after fitting with a

lid, the latter is heated until the salt fuses smoothly and without bubbles. The loss of weight in this operation represents the amount of water present. A quantity of freshly-dried powdered sulphate of lead, amounting to eight or ten times the weight of the saltpetre, is then placed upon the latter, and the crucible is again weighed. It is now placed over the lamp and gently heated, when decomposition ensues as follows:—

As soon as the crucible becomes hot, red-colored fumes of nitrous acid are seen to escape from under the lid; when this has ceased, and no more can be detected by the smell, the lid is lifted. Should any nitrous vapors remain in the crucible, the heat is continued a little longer. After cooling, the crucible is weighed, and the loss sustained gives the amount of nitric acid contained in the salt. Every fifty-four grains of nitric acid thus liberated represent one hundred and one grains of pure nitrate of potassa. This process is recommended not only for its accuracy, but also for the simplicity of its manipulation, and the short time required for its performance. The presence of chlorides, sulphates, or earthy matters does not in the slightest degree interfere with its application; but should the total amount of impurities exceed five per cent., it is necessary to mix the saltpetre with about four or five times its weight of the lead-salt in a small mortar, and after having transferred the mixture to the crucible, to rinse the mortar with small quantities of the reagent, which are then placed on the top of the first in the crucible.

The quantity of sulphate of potassa contained in saltpetre is determined by taking a weighed portion, dissolving in water, acidulating the solution with nitric acid, and adding nitrate of baryta as long as a precipitate is produced. Every 116·6 grains of sulphate of baryta thus obtained represent eighty-seven grains of sulphate of potassa. The amount of chloride of potassium is estimated by adding to a solution of another portion, nitrate of silver. Every 143·5 grains of chloride of silver produced, indicate 74·5 grains of chloride of potassium. Lastly, the quantity of insoluble matter is determined by dissolving a given weight of the sample in water, filtering, washing, and drying the insoluble residue, and weighing it.

Should the saltpetre under examination be contaminated with chloride of sodium, or, still more detrimentally, by nitrate of soda, the above methods of estimation do not give accurate results. In this case, it is necessary to determine the respective quantities of the two bases—potassa and soda. This is effected most conveniently by converting these bases into anhydrous sulphates, and weighing. The dry mass is then redissolved in water, and the sulphuric acid estimated by precipitation as sulphate of baryta. Now, as one hundred parts of sulphate of potassa give one hundred and thirty-four of sulphate of baryta, whilst the same amount of sulphate of soda gives one hundred and sixty-four parts of the barytic salt, it is evident, that if the weight of the mixed sulphates of the alkalies, together with that of the sulphate of baryta, be known, the respective quantities of potassa and

soda may be easily ascertained. Thus, if a larger quantity of sulphate of baryta be obtained than the ratio 134 : 100, the excess would be due to the salt of soda, from which the quantity of soda existing in the sample in the state of nitrate may be calculated, since every one hundred parts of sulphate of soda represent 119·7 of the nitrate.

The principal use of saltpetre in the arts, is in the production of gunpowder, for an account of which the reader is referred to page 335, *et sequitur*. In the East Indies it is employed for the preparation of cooling mixtures. On account of its powerful antiseptic properties, it is much used in the preservation of meat and animal matters in general. In the laboratory of the chemist, nitrate of potassa is chiefly employed as an oxidising agent. It is used also in the preparation of lucifer matches. The physiological effects of nitrate of potassa are, in small doses, diuretic and sedative; in doses of from half an ounce to one ounce, it is poisonous, exciting spasms, vomiting, bloody stools, convulsions, and in many cases death.

CHLORATE OF POTASSA.—This salt, when first prepared, was confounded with the one just described, but was distinguished as a peculiar salt by BERTHOLLET in 1786. The Editor finds it is most economically prepared by exposing equivalent proportions of carbonate of potassa and hydrate of lime to a current of chlorine. During the absorption of the gas the mass becomes hot, and evolves water; when saturated, it is gently heated to complete the decomposition. The fol-

lowing equation represents the change : $6 \text{ KO}, \text{CO}_2 + 6 \text{ Ca O HO} + 6 \text{ Cl} = 5 \text{ K Cl} + 6 \text{ Ca O}, \text{CO}_2 + \text{KO}, \text{Cl O}_5 + 6 \text{ HO}$. By treatment of the mass with water, the carbonate of lime is separated, and the chlorate of potassa is then freed from the more soluble chloride of potassium by evaporation, and repeated crystallization. The usual method of preparing this salt is by passing chlorine slowly through a solution of carbonate of

Fig. 424.

lowing equation represents the change : $6 \text{ KO}, \text{CO}_2 + 6 \text{ Ca O HO} + 6 \text{ Cl} = 5 \text{ K Cl} + 6 \text{ Ca O}, \text{CO}_2 + \text{KO}, \text{Cl O}_5 + 6 \text{ HO}$. By treatment of the mass with water, the carbonate of lime is separated, and the chlorate of potassa is then freed from the more soluble chloride of potassium by evaporation, and repeated crystallization. The usual method of preparing this salt is by passing chlorine slowly through a solution of carbonate of

In proportion as the quantity of chlorine increases, the bicarbonate becomes decomposed, carbonic acid is eliminated, and an additional quantity of hypochlorite

of potassa is produced. When the solution is strongly charged with hypochlorite, the action of the chlorine on the potassa salt is changed. Thus:—

The residual liquor, after crystallization of chlorate of potassa, contains, besides a small proportion of this salt, a considerable quantity of hypochlorite of potassa and chloride of potassium.

Manufacture.—Chlorate of potassa is now produced on a large scale by the following method, which has been found to answer better than any other. One part of chloride of potassium and two parts of hydrate of lime are reduced with water to a thin cream, and chlorine gas—prepared in the ordinary way from binoxide of manganese and hydrochloric acid—passed through the menstruum till it assumes a pinkish color, which is due to the formation of traces of hypermanganic acid.

A little manganese passes over during the operation, and when no more chlorine is required for the alkaline bases, water is decomposed and hypermanganic acid produced. The annexed equation represents the principal change:—

The vessel holding the solution is of any convenient form, and is provided with agitators of all shapes and sizes, depending upon the whim or caprice of each

manufacturer. It is connected with a similar one containing a fresh charge of the same materials, by means of a waste-pipe, through which all the escaping gas passes to be there absorbed. When the liquor in the former is ready to be drawn off, the gas is made to enter the latter, and the connecting-pipe between the two cisterns takes the unabsorbed chlorine to the first vessel, which, when empty, is re-filled immediately, so that very little time or gas is lost. The saturated liquor is, when drawn off, evaporated to 34° Twaddell, and the mother-liquor to 46°, if two crops of crystals are desired; if only one, then the menstruum is at once evaporated to 60°. The crystals, after being well washed, are drained on a cone having a small aperture at the bottom, and are afterwards dried upon iron plates heated by steam. The chloride of calcium is the only other compound present. Some manufacturers re-crystallize them, so as to produce a first-rate article. The principal manufacturers of this salt are, ALBRIGHTS of Birmingham, GAMBLES of St. Helen's, JAMES MUSPRATT and SONS of Liverpool, and FREDERIC MUSPRATT of Woodend, near Warrington, Lancashire. The annual production is nearly five hundred tons. The principal use to which it is applied are in bleaching, making lucifer matches, and for pyrotechnic purposes.

The Editor thinks that some means might be adopted for using this salt in the bleaching of palm oil, *et cetera*, instead of the chromate; it is cheaper, and it contains more of available oxygen.

Properties.—Chlorate of potassa— KO, ClO_3 —is a colorless, transparent, anhydrous, crystalline salt, having a glassy lustre. The crystals are oblique rhombic prisms. The taste of the salt is cooling and austere. If it be triturated, it appears phosphorescent. When heated to between 400° and 500°, it decrepitates and fuses; at a stronger heat, it loses the whole of its oxygen, leaving a residue of chloride of potassium. According to GAY-LUSSAC, it is soluble in thirty-three parts of water at 32°, in seventeen at 59°, and in five parts at 212°. It is slightly soluble in alcohol. Its action upon many combustible bodies is very energetic, and when rubbed with charcoal, sulphur, and phosphorus, the mixture inflames and explodes. Its principal use is in the manufacture of lucifer matches, and percussion powder for gun caps. It was proposed by BERTHOLLET as a substitute for saltpetre in the manufacture of gunpowder, and the attempt was made at Essone in 1788; but no sooner was the mixture of the chlorate with the sulphur and charcoal submitted to trituration, than a violent explosion took place, which proved fatal to several persons. Chlorate of potassa has also been used in medicine for imparting oxygen to the system; but, curious to say, as shown by WÖHLER, it passes off by the kidneys unaltered, and according to CHRISTISON, has no physiological or therapeutic action whatever.

CHROMATE OF POTASSA.—This salt, though much more important as a compound of chromium than of potassium, yet requires to be noticed under this head. The metal, *chromium*, so called from its tendency to produce colored salts, the name being derived from the Greek word signifying color, was discovered by VAUQUELIN in 1797, in the examination of red chromate of lead from Siberia. The most important native compound

of this metal is a combination of oxide of chromium and iron, commonly termed chromate of iron, which is found abundantly at Unst in Shetland, and in other parts of Europe and America. DUMAS directs chromate of potassa to be prepared from the double oxide of chromium and iron— $\text{FeO} + 2\text{Cr}_2\text{O}_3$ —as follows:—The ore is to be pulverized and mixed with an equal weight of nitrate of potassa, and the mass gradually heated to redness. In this operation, chromate, silicate, aluminate, and occasionally manganate of potassa are produced, and the oxide of iron is set free. The soluble salts contained in the mixture are extracted by washing, and the residue, which still contains chromium, is digested with hydrochloric acid—which dissolves the oxide of iron and alumina—and again heated with nitre as before. The aqueous solution is then exactly neutralized with nitric acid, and by evaporation the alumina and silica are separated. The crystals of chromate are then freed from those of nitrate of potassa, and purified by recrystallization. It is important in the preparation of this salt to use a very small proportion of saltpetre, so that the whole of the alkali may combine with chromic acid, and constitute a neutral chromate; to oxidise the whole of the chromium, the fusion is repeated with those portions of the ore unattacked by the first operation. The process for the manufacture of chromate of potassa has lately been rendered more economical by the substitution of lime for the nitrate in the preliminary calcination. A mixture of the chrome iron ore and lime or chalk in very fine powder, being calcined, oxygen is absorbed, and a chromate of lime formed, which is extracted from the mass by water. The solution is then decomposed by means of a potassa salt, and the chromate of potassa produced is separated from the calcareous compound by crystallization in the usual manner.

Properties.—Chromate of potassa— KO, CrO_3 —is deposited from a concentrated solution in small prismatic anhydrous crystals. It has an unpleasant metallic taste, and an alkaline reaction. It is very soluble in boiling water. At 60° this liquid dissolves half its weight of the salt. In alcohol it is insoluble. Its coloring power is so great, that one part gives a distinctly yellowish hue to forty thousand parts of water. As met with in commerce, chromate of potassa frequently contains sulphate; the sophistication may be detected by acidifying a solution of the salt with hydrochloric acid, and adding chloride of barium, when, if a sulphate be present, insoluble sulphate of baryta precipitates. The principal use of this salt is in the preparation of the chromates of lead, zinc, *et cetera*, which are extensively employed in painting, and the former also as an oxidising agent in the ultimate analysis of organic substances.

BICHROMATE OF POTASSA.—This salt is of great importance in the arts and manufactures, and especially in calico printing. By a reference to the article on DYEING, Vol. I., page 643, *et sequitur*, the reader will become acquainted with the variety of purposes to which it is applied in this most useful and beautiful art. The principal manufactories of the bichromate or *chrome* are at Glasgow. It is obtained from the salt last described by adding a sufficient quantity of acid—usually sulphuric—to impart to the solution a sour

taste. The mixture is then set aside for a few days, when deep orange-red crystals are deposited. The change may be thus represented— $2\text{KO}, \text{CrO}_3 + \text{SO}_3 = \text{KO}, 2\text{CrO}_3 + \text{KO}, \text{SO}_3$. The use of nitric acid is much to be preferred; as if sulphuric acid be employed there is considerable difficulty in separating the sulphate from the chromate, while if nitric acid be employed the nitrate of potassa produced, being much more soluble than the bichromate, admits of more easy separation. For the same reason, if acetic acid be taken the salt is obtained in a still greater degree of purity. Owing to the higher value of these acids, however, they will probably never entirely supersede sulphuric acid in this manufacture.

Properties.—Crystallized bichromate of potassa— $\text{KO}, 2\text{CrO}_3$ —has the form of quadrangular prisms and tables, is anhydrous, permanent in the air, and of a beautiful orange-red color. The crystals are soluble in about ten times their weight of water at 60° , and much more so in boiling water. When heated to redness, they fuse without decomposition into a transparent red liquid, which on cooling concretes to a crystalline mass, and, owing to the unequal contraction of the crystals, afterwards crumbles to powder. At a white heat a portion of the chromic acid is reduced to a lower oxide, and the residue consists of sesquioxide of chromium, and neutral chromate of potassa. When this salt is dissolved in hydrochloric acid, and the solution boiled, a salt is produced containing an equivalent of chloride of potassium united to two of chromic acid— $\text{KCl}, 2\text{CrO}_3$ —in which the chloride of the alkaline metal acts as a base to the chromic acid. According to GREGORY, both chromates of potassa have a very deleterious action on the system when their solutions are frequently brought in contact with the skin—producing sores which are painful and difficult to heal. Bichromate of potassa is occasionally employed in conjunction with chromate of lead as a source of oxygen in organic elementary analysis. The solution of both chromates is possessed of powerful antiseptic properties. Large quantities of this salt are used in the bleaching of palm oil as a source of oxygen, which is liberated as follows:

CHLORIDE OF POTASSIUM.—This salt may be prepared by inclosing potassium in chlorine gas, when the metal takes fire, burning even more brilliantly than in oxygen, and at the same time combination ensues between the two elements. It is formed also when potassa or its carbonate is dissolved in hydrochloric acid—in the case of the latter with evolution of carbonic acid. As, however, this salt is frequently obtained as a by-product in several chemical and pharmaceutical operations, it is seldom necessary to prepare it directly. As previously noticed, it is obtained in considerable quantities in crude saltpetre and in pearl ash, and exists also in the mother liquor of the chlorate of potassa. From these sources it may readily be obtained in a state of purity by successive crystallizations.

Properties.—Chloride of potassium— KCl —is an anhydrous salt, the form of the crystal of which is cubic. It has a saline and slightly bitter taste; dissolves in three parts of water at 60° , and in a much less quantity of boiling water. It is insoluble in alcohol. When heated, it decrepitates, and at a red heat fuses without decomposition. At a very high temperature, in open vessels, it slowly volatilizes in the form of white fumes, but in a covered vessel may be intensely heated without perceptible loss. Chloride of potassium is a salt of great importance in the arts on account of the facility with which it is transformed into other salts of potassa; hence, its use in the decomposition of the nitrates of lime, *et cetera*, in the production of salt-petre. It is also equally valuable in the preparation of potassa alum.

IODIDE OF POTASSIUM.—This important salt, like the chloride, may be prepared directly by combining the two elements, by heating them in contact with each other. The various methods for procuring it on the large scale, its properties, actions, and uses in the arts, have been detailed under the article IODINE, to which the reader is referred.

BROMIDE OF POTASSIUM.—Bromine and potassium are contained in sea-water, but whether the bromine is in combination with potassium or with some other metal, as, for example, sodium or magnesium, has not yet been ascertained, so difficult is the problem.

The process of the London college is the one usually followed in the preparation of this salt. One ounce of iron filings, and afterwards two ounces of bromine, are added to one and a half pints of water, and the mixture is allowed to stand for half an hour, constantly agitating. A gentle heat is then applied until a greenish color is developed. A solution containing two ounces and one drachm of carbonate of potassa to a pint and a half of water, is then added, and the precipitate of carbonate of iron produced is removed by filtration; and by evaporation of the filtrate the salt is obtained in crystals. In this process a bromide of iron is first formed, which is then decomposed by the carbonate of potassa, thus:—

Another method of procuring this salt consists in adding to a hot solution of potassa, as much bromine as the liquid will dissolve. A brownish fluid is thus produced, through which sulphide of hydrogen is passed until it becomes colorless. Gentle is the heat then to be applied to expel the excess of the latter reagent, and the sulphur which has precipitated is removed by filtration. The filtrate on evaporation will then yield crystals of bromide of potassium. The action of bromine upon a solution of potassa is analogous to that of chlorine, as noticed under chlorate of potassa, and may be thus expressed:—

When sulphide of hydrogen is passed through a solution containing bromate of potassa, decomposition ensues, the hydrogen of the gaseous acid abstracts the

whole of the oxygen from the bromate, and, at the same time, the free sulphur precipitates, thus :—

The filtered solution contains, therefore, only bromide of potassium. Occasionally a modification of this latter process is employed, in which the oxygen of the bromate of potassa is removed by heating the salt to redness, instead of by the sulphide of hydrogen.

Properties.—Bromide of potassium—K Br—crystallizes in cubes or rectangular four-sided tables, has a sharp, pungent, saline taste, and is persistent in the air. When heated, it decrepitates, and at a red heat fuses without decomposition. It is very soluble in water, and slightly so in alcohol. At a red heat it is decomposed by chlorine, but not by iodine; and bromine is also disengaged in the cold by the mineral acids.

Adulteration.—Commercial bromide of potassium frequently contains chloride, and sometimes also iodide of potassium. The presence of the latter is most conveniently detected by the addition, to an aqueous solution of the salt, of protochloride of palladium, which in presence of iodide gives a brownish-black precipitate. Nitrate of protoxide cannot be substituted for the chloride of palladium, as in this case bromine is also precipitated. The most frequent adulteration, however, is with chloride of potassium, and yet the London college gives no test for the detection of this sophistication. The best method is that suggested by Rosé, and is conducted as follows :—The suspected salt is mixed with an excess of bichromate of potassa, and introduced into a tubulated retort with the addition of concentrated sulphuric acid, and a receiver is adapted, containing aqueous ammonia. On the application of heat, if the salt be pure, only bromine distils over, and the volatile alkali remains perfectly colorless. If, however, a chloride be present, *chloro-chromic* acid also passes over, and the ammonia becomes yellow; and in the solution chromic acid may now be detected by the production of a yellow precipitate, on addition of acetate of lead.

Physiological effects.—Bromide of potassium is a diuretic and cathartic. Like the preparations of iodine, mercury, *et cetera*, it appears to exercise that influence over the nutrition of the body designated by the terms, resolvent, alterative, and deobstruent. Under its continued use, PEREIRA states that enlargements of the spleen and liver, and swellings of the lymphatic glands have disappeared; and Dr. WILLIAMS is of opinion that it possesses unusual, if not specific powers, in the cure of diseases of the spleen. It has also been used advantageously in scrofulous tumors, and in bronchocele.

CYANIDE OF POTASSIUM.—This useful salt is most advantageously prepared from ferrocyanide of potassium or yellow prussiate of potassa, which is to be carefully desiccated, and reduced to fine powder, eight parts of which are mixed with three parts of carbonate of potassa and one of charcoal, both in impalpable powder. This mixture is to be exposed to a strong red heat in a closed

iron crucible. After cooling, the mass is to be finely powdered, placed in a funnel moistened with a little alcohol, and then washed with cold water. The colorless strong solution of cyanide of potassium which passes through, is then rapidly evaporated to dryness in a porcelain basin and fused at a red heat. This salt, as obtained by ignition of the above ingredients, without the charcoal, usually contains a little cyanate, which, however, does not interfere with its use for forming and dissolving cyanides of gold and silver for the processes of voltaic gilding and plating.

The preparation of cyanide of potassium in a state of perfect purity, is always attended with difficulty, owing to the action of the carbonic acid of the air upon its solution, and the tendency of the menstruum itself to undergo spontaneous decomposition, even when secluded from the air. It is obtained in a state of great purity by adding absolute hydrocyanic acid, or a strong solution of this acid, to an alcoholic solution of potassa; a portion of the cyanide falls down as a white crystalline precipitate, which should be washed with alcohol and dried. An additional quantity may be obtained from the mother liquor by evaporation of the latter in a retort. Cyanide of potassium crystallizes in colorless cubes, which deliquesce in damp air, at the same time becoming opaque. It is very soluble in water. In close vessels it may be heated to redness without alteration, but by exposure to the air absorbs oxygen, and becomes cyanate of potassa—KO, Cy O. The purity of this cyanide is best ascertained by its property of dissolving the red oxide of mercury, twelve grains of the pure salt dissolving twenty of the finely-pulverized mercurial salt. The principal use of cyanide of potassium is in electro-plating and gilding, also in photography. Being similar and equally powerful in its action upon the animal economy with hydrocyanic acid, and as the dry salt may be preserved in a well-stopped bottle without change, it might be substituted with advantage for the latter in medicine, as the acid so readily undergoes decomposition.

Ferrocyanide and ferricyanide of potassium, termed also yellow and red prussiate of potassa, are respectively compounds of the metal potassium, with the salt radicals, *ferrocyanogen*—Fe Cy₃, and *ferricyanogen*—Fe₂ Cy₆. The preparation, manufacture on the large scale, properties, *et cetera*, of these salts have been fully discussed under the article IRON, Vol II., page 451 *et seq.*

SULPHOCYANIDE OF POTASSIUM.—This salt is a combination of potassium with the salt-radical sulphocyanogen Cy S₂ = Csy. It is present in the saliva of man and some other animals. It is prepared by heating the powdered anhydrous ferrocyanide of potassium with an equal weight of powdered sulphur in an iron pot. The mixture is kept in a fused state for half an hour, at a temperature above the melting point of sulphur, but below that at which bubbles of gas rise through the melted mass. The latter consists of a mixture of sulphocyanide of potassium and sulphocyanide of iron, with the excess of sulphur. This is treated with water, the insoluble matters removed by filtration, and to the colorless or slightly red filtrate, first heated to boiling, carbonate of potassa is added as long as a precipitate is produced. The liquid filtered

from this precipitate, on evaporation, yields crystals of sulphocyanide of potassium, from which any adhering carbonate of potassa may be removed by solution in alcohol.

Sulphocyanide of potassium— $K\ Cy\ S_2$ —crystallizes in long white striated prisms, which are anhydrous, and resemble nitrate of potassa in appearance and taste. They deliquesce in a moist atmosphere, and are very soluble in hot alcohol, from which the salt crystallizes on cooling. Sulphocyanide of potassium communicates a deep port-wine color to strong solutions of sesquioxide of iron, and is, consequently, much employed as a test for that metal in its higher state of oxidation. Nitric acid must not be present when testing for iron with this reagent. The Editor considers the sulphocyanide a very beautiful indication of the presence of iron. In the most dilute solutions a red coloring is at once apparent.

BITARTRATE OF POTASSA—Tartar—Argol—Cream of Tartar.—This salt is a constituent of many vegetables, and especially of the grape. The substance known as argol or crude tartar, consisting of bitartrate of potassa, tartrate of lime, and coloring matter, is found as a concretion upon the inside of wine casks, in which newly-made wine has been kept for some time. From this deposit the pure salt is obtained. The following is the process of purification pursued at Montpellier, as described by FIGUES:—The argol is boiled in water, and the solution allowed to cool; the crystalline deposit thus obtained is washed with cold water, and then redissolved in boiling water, to which is added pipe clay to the amount of five per cent. of the weight of the salt, together with a small proportion of animal charcoal. The addition of these substances promotes the separation of coloring matter. When the latter has completely subsided, the clear liquor is allowed to cool slowly, when crystals of the pure bitartrate separate. At Venice, the process of purification consists in the separation of the grosser impurities by repeated solution and recrystallization of the salt, after which white of egg and wood ashes are added to the boiling solution of the crystals, and during the effervescence which ensues the impurities rise to the surface and are skimmed off. According to DUFLOS, the crystals are most readily freed from lime by placing them in contact with dilute hydrochloric acid, and subsequently draining and washing them.

Bitartrate of potassa— $KO, 2\bar{T}$ —as usually met with, forms a white crystalline mass, having an acid and gritty taste. The crystals, which are irregular six-sided prisms, contain one equivalent of water, which is not given off at a heat much below the point at which the salt is decomposed. Water at 68° dissolves the one hundred and eighty-fourth part, and at 212° one-fifteenth of its weight. When heated, bitartrate of potassa swells up, evolves various volatile products, gives out an odor of caromel or burnt sugar, and a mixture of charcoal and carbonate of potassa, termed *black flux*, remains. Heated with an equal weight of nitrate of potassa, it leaves a residue of pure carbonate of potassa.

Powdered bitartrate of potassa, or cream of tartar, is frequently adulterated with various white mineral and organic powders. The proofs of its freedom from these

are complete solubility in water, and, according to the Edinburgh College, its decomposing power over nitrate of lead. The principal use of bitartrate of potassa is in dyeing, owing to its power of dissolving metallic oxides. It is used also in medicine.

Physiological Effects.—In small doses this salt has a refrigerant and diuretic action; in doses of half an ounce it forms a brisk yet gentle purgative. It is frequently used in admixture with sulphur as a mild laxative. In excessive doses it produces inflammation of the stomach and intestines.

Of other organic salts of potassa, none, with the exception of the oxalate and acetate of potassa, are used to any great extent in the arts or manufactures. These latter are prepared by saturating a solution of carbonate of potassa with the respective acid, and evaporating to the crystallizing point, or to dryness. Oxalate of potassa— $KO, C_2O_3 + HO$ —is used in the laboratory principally in the estimation of manganese ores. An acid oxalate—termed *salt of sorrel*, or *salt of lemons*—is employed to remove ink-stains and iron-moulds from linen. Acetate of potassa— $KO, C_4H_3O_3 = KOA$ —is chiefly employed in medicine.

ANALYSIS.—The salts of this metal are distinguished from all other substances by the following tests:—Sulphide of hydrogen, sulphide of ammonium, and alkaline carbonates, effect no change in their solutions. *Tartaric acid*, added in excess to a solution of a potassa salt, produces, especially after violent agitation, a white, crystalline, quickly-subsiding precipitate of bitartrate of potassa. *Perchloric acid* has a similar effect. *Fluosilicic acid* affords a transparent, gelatinous precipitate, which, when it subsides, is iridescent, and dries into a white powder. An alcoholic solution of *picric acid* throws down sparingly soluble yellow crystals of picrate of potassa. When heated on a platinum wire before the blowpipe, potassa salts communicate a characteristic violet or purple tinge to the flame. This reaction is obscured by salts of soda. By the test recommended by HARKORT, potassa salts may, however, be detected before the blowpipe when soda salts are also present. It depends upon the fact, that oxide of *nickel* when fused with borax in the blowpipe flame, gives a brown glass; and this glass, when melted with a potassa salt, becomes blue. Of all the tests for the detection of potassa salts, *bichloride of platinum* is, however, the most delicate. This reagent produces, in solutions of these salts, a yellow crystalline precipitate of bichloride of platinum and chloride of potassium— $Pt, Cl_2 + KCl$. In applying this test, the *absence of salts of ammonia* must be previously ascertained, as these give rise to an analogous precipitation. A little hydrochloric acid is added collaterally with the bichloride of platinum, and if the precipitate does not appear after a short time, the mixture is evaporated to dryness at 212° ; and if potassa be present, on the addition of spirit of wine, the double chloride is left in the form of yellow shining crystals.

ESTIMATION.—In the determination of salts of potassa, they are almost invariably converted into the state of bichloride of platinum and chloride of potassium. The estimation is effected as follows:—The salt, first converted into chloride, is mixed with hydro-

chloric acid and bichloride of platinum in excess, and the mixture is evaporated to dryness at 212°. To the residue alcohol is added, and after standing some time, the whole is thrown upon a weighed filter, and the insoluble double salt of platinum and potassium is affused with spirit, until the washings leave no residue on evaporation. The salt is then dried and weighed. Every 243·5 grains of bichloride of platinum and chloride of potassium thus obtained, represent thirty-nine grains of potassium, or forty-seven of potassa.

It not unfrequently occurs in chemical investigations that a salt of potassa, and one of soda, exist collaterally, and it is desired to estimate the relative proportions of each. In such a case, the most convenient method is as follows:—The two bases are converted into sulphates by any available means, and weighed in this condition. After noting the weight, the mixed salts are redissolved in water, and treated with a solution of chloride of barium. The precipitate of sulphate of baryta thus obtained is collected by filtration, washed, dried, ignited, and weighed. From these data the respective quantities of soda and potassa may now be calculated; for, as one hundred parts of sulphate of potassa give one hundred and thirty-four of sulphate of baryta, and one hundred parts of sulphate of soda afford one hundred and sixty-four of sulphate of baryta, the larger quantity of the latter salt obtained than the ratio 134 : 100—is due to the salt of soda, and the proportion of the latter base present may easily be calculated, since one hundred parts of sulphate of soda represent 43·7 of soda. The proportion of potassa is then known by deducting the quantity of sulphate of soda found from the weight of the mixed sulphates. Every one hundred parts of sulphate of potassa remaining, represent fifty-four of potassa.

POTTERY.—*Potterie*, French; *steingut*, *porzellan*, *töpfen*, German.—The earliest exponents of the potter's art supply indubitable, and, in some respects, unique data, for elucidating the theology, the literature, the manners and customs of the most remarkable nations of antiquity. Hence, from this cause alone, the history and practice of this art excite a deep and peculiar interest, irrespective of any other considerations to which its operations may give rise. These, however, are such as present their own special claim to notice, since the art itself, in its varied and comprehensive application, embodies the most complete and perfect medium for the exhibition of industrial skill. No branch of manufacture presents so ancient and intimate an alliance between art and utility as that of the potter. One of the most ancient and characteristic channels of national industry, the production of pottery takes its rise from a date which, in the Eastern hemisphere, is lost in the darkness of remote antiquity. The extreme plasticity of certain earths and their almost universal diffusion; the ease with which they can be fashioned into forms suited to ordinary domestic requirements; the consistency also which even natural heat will impart to them—have necessarily conduced to the general adoption of this class of manufactures, even in the primitive stages of savage life. The peculiar condition of plasticity, from the earliest ages, has rendered the potter's clay the most obvious material for the

gratification of that inherent desire to form or model the lineaments of some ideal image, or some palpable reality, which is a distinguishing characteristic of man's nature, and is patent as well in the infancy of society as in the early days of any individual. At what period the indulgence of a mixed mimetic and creative faculty was first applied to meet the requirements of primitive life, is a point of chronology that can never be exactly determined. As well might the Editor attempt to pen a diary of the reminiscences of his childhood, or chronicle the months and days when he drew figures on the sand, as seek to investigate and define the original invention and first production of pottery. BRONGNIART urges that when the antiquity of an art may be established by a train of simple reasoning and by the most natural deductions, one is not to evade admitting the fact through the fear of appearing to rest content with common and ordinary considerations. This observation is very happily applicable in the instance of pottery. Monuments, almost infinite in number and variety, the authenticity of which cannot be questioned, and so simple and clearly intelligible that no deep study is required to appreciate their interest and value—demonstrate that the potter's art, from primæval times, has been intimately associated with productions the most useful to man, as well as the most beautiful in themselves.

The ceramic art, both in its theory and its practice, unites a combination of qualities unknown in any other expression of human skill. No other industry presents so many divers considerations, all of them of the utmost interest, and each one rich in economic and scientific application. Finding its materials at the surface of the earth, pottery exhibits products the most simple and yet the most varied—the easiest to fabricate, but still, though fragile, of incomparable durability. Man, when in his weakest and most isolated condition, is able to extract clays for pottery from the ground beneath his feet; these materials, the spontaneous gift of nature, he fashions on the instant in accordance with his will; and, without either science or preparation, he even gives to them forms of a hardness sufficient to satisfy the first demands of social refinement. The products of these substances—so simple in their character, so abundant, so easy to bring together, so readily endowed also with every quality best calculated to facilitate their practical application—are absolutely endless in their variety, while, in their most successful exponents, their beauty may be pronounced matchless. Every species of form—from the classical severity of the early Greek period to the florid luxuriance of the wares of Saxony, France, and, one may now fairly add, England—here finds a fitting and worthy medium. Artistic excellence, both in the painter and the modeller, can here develop its highest capabilities. A material, which science teaches to present the most lustrous surface, which is solid, imperishable, and admirably qualified for the application of varied and brilliant colors, offers such inducements to the painter for the practice of his art, that the pencil of the glorious RAFFAELLE himself was occasionally employed in its decoration.

The potter's wheel, an implement identified with the

most important class of fictile productions, may have been the first piece of mechanism invented by the grandsons of NOAH, and originally employed while the earth was yet moist from the waters of the flood; or it may have been produced in various parts of the antediluvian world, long before the tremendous visitation of the deluge. Certainly the most ancient mechanical appliance that industrial art has adapted to its use, the potter's wheel is no less distinguished for its simplicity; and, at the same time, it exhibits so perfect a contrivance for imparting, under expert direction, beauty and utility to shapeless masses of matter, that it has descended from age to age to the operator of the present day without any important modification. Indeed, so absolutely identical is the mode of working, with reference both to the mechanical and the manipulatory processes now in use in this primitive branch of fictile art, with the system prevalent some thousands of years before the Christian era, that were it possible to resuscitate the mummy of an ancient Egyptian thrower, he might immediately find lucrative employment with the MINTONS, COPELANDS, CHAMBERLAINS, KERRS, and others, of the present day. According to Genesis, one is warranted in concluding that the potter's wheel was known to all the early families, and that it was retained and used by them when they had been dispersed abroad over the face of the earth.

In countries where the drying influences of the sun and air are pre-eminently powerful, the desiccation of clays after rain must necessarily have attracted attention. The plastic nature of these simple substances while in one condition, and their compact mass when in another, together with the ease with which in the former state they could be manipulated, and in the latter, fixed into form, cannot fail, at an early period, to have indicated their applicability to those useful purposes that provide for some of the most urgent requirements of human life. The want of vessels that would contain liquids, and also resist the action of fire, would naturally arouse the exercise of man's inventive powers. The hard shells of certain vegetal productions, such as gourds and the larger kinds of nuts, together with the skins of animals, might be easily transformed into recipients for fluids. The preparation of these materials, however, implies the possession of tools, together with a previous knowledge of some elementary manual arts. But then, such vessels being obtained, and the action of fire and its use in the preparation of food being understood, but little of real assistance could thus be acquired. Vessels of this description would scarcely be competent to render available the known services of fire. In such circumstances, some savage tribes have been constrained to adopt the expedient of dropping hot stones into the liquids in their frail vessels, in the hope of so imparting to them some degree of warmth—a dilatory and unsatisfactory process, and one that would be gratefully abandoned upon the discovery that certain earthen substances possessed the property of resistance to the action of fire.

Whether the fashioning and hardening of clay was first practised by the potter or the brickmaker, must ever remain a matter of speculation. Probably both uses

of the common material were discovered about the same period, and under the same circumstances. Bricks, *thoroughly burned*, it is known, were employed at the building of Babel, two thousand two hundred years before the Christian era. And, again, it is also certain that pottery, properly so called, had attained to an important condition of usefulness in very remote ages, since the earliest authentic records allude to the potter's wheel as an implement, even then, of high antiquity. In all parts of the habitable globe the same requirements would be felt; and as similar means for satisfying them would everywhere abound, men would naturally be prompted to the exercise of that kindred ingenuity, which had been implanted alike in them all as a universal heritage: and thus, amongst races rude and uncultivated, and in all other respects utterly ignorant of the arts that minister to human convenience, it has been satisfactorily traced that earthen vessels had been in use centuries before the existence of any such people was conjectured. Vases, for example, have been discovered amongst the aboriginal Indians on the Musquito shore, which by them were treasured as vestiges of antiquity; and there is every reason for believing that these fictile works were the production of the ancestors of the people amongst whom they were found, since the remains of ancient potteries exist far up the Black River in that region. PLATO describes the ceramic art as amongst the earliest on record. VITRUVIUS, again, affirms that in the Augustan age the Romans made their water-pipes of potters' clay; and after the Roman conquest potteries were established in England, where the fabrication of similar pipes for the same purpose was introduced. These pipes were about two inches in thickness, and firmly joined together with common mortar, mixed with oil; and, to prove both the durability of the material, and the tenacity of the compound, some relics that were dug up about a century ago in Hydepark, London, were found to be in the most perfect condition, and as well suited for their use as when they were at first manufactured. A claim has been advanced on the part of the ancient Britons to a knowledge of the art of working pottery anterior to the Roman invasion; and the fact that cinerary urns of earthenware have been repeatedly exhumed from Celtic barrows in different parts of the kingdom, tends to warrant the assertion. Many writers are inclined to the opinion that the aboriginal Britons were indebted for these works to the Venetians. There appears no reason, however, for withholding from our Celtic forefathers the credit of having produced their own rude pottery, at a period antecedent to the earliest visit paid to their shores by adventurous and enterprising voyagers from lands lying nearer to the sun-rising. Remains of considerable Roman potteries are to be traced in various parts of England, and especially in Staffordshire, on the site of the great potteries of the present day.

There is something strangely suggestive in the relics of ancient pottery-kilns that still linger on the scene of their former active operations. The modern Staffordshire potter has derived no heritage from his Roman predecessor. There had been no continuity of work. Centuries of disuse had obliterated the very memory

of those remote artificers, and tradition had not even whispered of their scene of action. The potter established himself in Staffordshire, altogether unconscious of his vicinity to the spot in which long-buried laborers in his own handicraft had exercised their mutual calling. He saw that the natural materials suitable for his purpose were there abundant; and, having settled down, he plied his wheel, and threw his clay, and burned his pots—absolutely ignorant the while that he was reviving operations with which that district, in ages long past away, had been familiar. It was not until after many years of laborious occupation, that the upturned fragments of unwonted vessels casually revealed the ruins of an ancient furnace, and significantly declared that the potter's wheel was again revolving above the potter's tomb.

The antiquity and the nobility of the potter's art is demonstrated by repeated references to it in Holy Writ, and especially in similitudes which emanate directly from the Divine imagery. Indeed, from Proverbs, the twenty-sixth chapter and twenty-third verse, one would almost be led to suspect that the art of glazing earthenware vessels had been discovered seven hundred years before the Christian era. The words are, Burning lips and a wicked heart are like a potsherd covered with silver dross. Now it is a well-known fact that silver is generally refined by means of lead; the two metals usually occur together, and if lead be strongly heated in an earthen vessel a partial glaze is communicated to the surface, and this probably led to the discovery of a glaze.

Not only do the Scripture texts now alluded to establish for the operations to which they refer a very early date, but, what adds materially to the peculiar interest of the principal and most essential processes, they show that the mode of fabrication remains up to the present time substantially the same. By the ancients also the plastic art was employed for the highest and noblest purposes. Homage to the dead, and victory to the living, were typified in the votive products of the potter's skill. Eminence in the art was distinguished by public patronage, and chronicled by poets and historians. The profession of ceramic artists was held in high honor, and a college of potters was established at Numa eight centuries before the Christian era.

The term *Pottery*, which is derived from the Latin *Poterium*, the name given by the Romans to drinking vessels, does not convey any signification that denotes either form or substance.

The word *Ceramic*, the generic title by which works in this department of art-manufacture are now known, is derived from the Greek. The Greek word, however, differs from its Latin synonym, in the circumstance that it primarily signifies the *horn of an animal*; and it has obtained its secondary and generally recognized signification from the early use of horns for drinking vessels, as also from the more or less literal adoption of the form of drinking-horns in the plastic materials with which such vessels have been fabricated. Representations of genuine *drinking-horns*, the primitive *ceramic* vessels, are of frequent occurrence in illustrations of ancient festivals; and, though they appear

much varied in their constructive details, the original type is distinctly apparent in them all.

The addition of the heads of animals at the extremity of the horns seems to have been very popular; and numerous examples are extant in which the heads of the eagle, dog, and other creatures, appear thus cumstanced.

The name thus originally applied to drinking vessels alone, was next adopted by the potter in reference to such of his productions as were designed for somewhat similar uses, and in which the same forms were introduced; and then it was gradually extended in its application, until it comprehended the entire range of fictile manufacture.

Notwithstanding the fact that articles of domestic utility were the first to exercise the skill of the potter, but little is known of the forms and composition of these earliest vessels. Their fragility indeed, coupled with their trifling intrinsic value, would naturally render it improbable that more than a few occasional relics should survive the period of their original fabrication. Some few primitive specimens still extant, that from their character seem obviously to have been destined for household uses, BRONGNIART objects to recognize in that capacity, in consequence of the permeable nature of the clay of which they are composed. But it may be suggested that this eminent savant would scarcely have advanced such an opinion, had not the early practice of saturating these vessels with oil for the purpose of obviating their porosity escaped his observation. The lapse of centuries and long disuse would have caused the total evaporation of the counteracting medium; but that porous clay, by the application of oil, may be rendered impermeable by ordinary liquids, does not admit a doubt.

It would naturally have been most desirable that a ceramic museum, or an essay on ceramic manufactures, should commence with examples of the first pottery that ever was made. This the very nature of the fictile art has rendered impossible; and yet, though the actual objects may be wanting, their pictorial representation has been preserved in the varied decorations of other and later productions of the same class; and thus, through the agency of pottery when in a more advanced condition, the image and purpose of the earliest works of the potter have been preserved and handed down to modern times.

Like the first rise of nations, the first applications of art and the original productions of manufacture are for the most part mythic and fabulous. After a while, probable traditions arise; and then, as the stream of time flows steadily onwards, veritable history at length stands confessed with well-defined lineaments. Such is precisely the condition of the ceramic art. The very weakness of its primitive elements is such as to baffle the most penetrating research. Gradually some works appear impressed with the capacity of endurance. In due time the number of these clay-constructed conquerors of time increases, and they assume variously diversified forms. There succeeds but a brief interval, before the history of pottery supplies one of its most graphic chapters to the history of mankind.

BRICKS.—The sun-dried products of Egypt, Assyria,

and Chaldea, embodying the earliest existing illustrations of fictile manufacture in its simplest application, are the only examples of their era that have survived the ravages of time.

The *brick*, without doubt, was one of the primitive efforts of plastic labor. Its geometrical form would of necessity be suggested by the want of some constructive materials, with which buildings might be erected with a greater uniformity of surface and precision of outline than could be obtained by rough coatings of mud. When once adopted, the palpable utility of bricks would render their introduction universal, and their use permanent. The use of bricks, indeed, has continued with but slight modifications from the building of the Tower of Babel to the present day.

BIRCH, in his learned History of Ancient Pottery, displays much research in treating upon the historical value attached to these silent, yet eloquent witnesses of the past. He affirms that the bricks of Egypt not only afford testimony to the truth of Scripture as to their composition of straw and clay; but also that, by the hieroglyphics impressed upon them, they transmit the names of a series of kings, and thus testify to the existence and date of edifices, all knowledge of which, except for these relics, would have utterly perished.

The bricks of Assyria and Babylonia, in addition to similar information, by their cuneiform inscriptions denoting the localities of the buildings for which they were made, have determined the sites of ancient Mesopotamia with a precision and completeness that could have been obtained from no other sources.

The general form of all these bricks is rectangular, those presenting a curved outline being of very rare occurrence. In so arid an atmosphere as that of Egypt, a country in which rain seldom falls, sun-dried bricks would effectually resist the action of any moisture to which they might be exposed, and they would endure for ages. VYSE states that the pyramids of Dashour, Illahoon, Howara, Abû Roash—the walls of Sais—the fortresses at Samneh, Centra Pselcis—the walls also of the Memnonium at Thebes, and the great wall that inclosed Egypt on the Eastern side from Pelusium to Heliopolis, a distance of one thousand five hundred stadia, or furlongs, were constructed of these sun-dried bricks. And, in addition to these more important works, the same materials were in constant use for the erection of private tombs and other edifices. Sir GARDINER WILKINSON adds that this material was employed in the great wall built by Sesostris across Egypt—the Gisir-el-Agoos—and for a small temple at Ekmin.

The rich alluvial soil of both the Delta and the Fayoum, at a remote period of Egyptian history, must have determined that the brick-manufacture should be established in those districts. The mud and slime yearly deposited by the Nile were peculiarly adapted for pottery purposes. BIRCH states that an analysis proves about one-half of the substance of this deposit to consist of argillaceous earth, one-fourth being carbonate of lime, while the residue comprises oxide of iron, carbonate of magnesia, and water. Close to the river's banks the deposit is much mixed with sand, which it loses in proportion as it is carried by the water further from them, so that at a certain distance

it consists of pure argil or clay, which at the present day forms excellent bricks, tobacco-pipes, and stucco. Amongst the earliest bricks in existence, those may undoubtedly be reckoned which were made for the construction of the various brick-built pyramids, although it is not possible at present to determine the relative antiquity of all these edifices. Several of them, however, have been ascertained to be tombs of monarchs of the twelfth dynasty. Bricks of this class, formed of Nile mud held together by chopped straw, continued to be manufactured in Egypt until about the tenth century before CHRIST.

The next step in the progress of the brick manufacture was the substitution of kiln-baked for sun-dried clay. An earthenware of a dull, coarse appearance, without any surface, polish, or glaze, was produced by this process; and it was employed for making sarcophagi, sepulchral cones, figures, vases, and other objects, in addition to the simpler bricks. All this baked pottery is *terra-cotta* in its simplest form. The external color is always some shade of red, though both the tint and the texture vary considerably in accordance with the degree of heat to which the pottery may have been exposed. A comparatively low temperature was sufficient for producing the soft pale tint, that appears to have been so generally preferred; in this condition, however, the *terra-cotta* is absorbent, though not sufficiently porous to allow water to escape. The absorbent property of this Egyptian *terra-cotta* is found to have been determined by the temperature of the furnace in which it was baked. The average size of the sun-dried bricks used by the ancient Egyptians was seventeen inches in length, eight inches in width, and in thickness five inches; those that were baked were generally somewhat smaller, and they appear to have been chiefly used in constructions that were exposed to a contact with water.

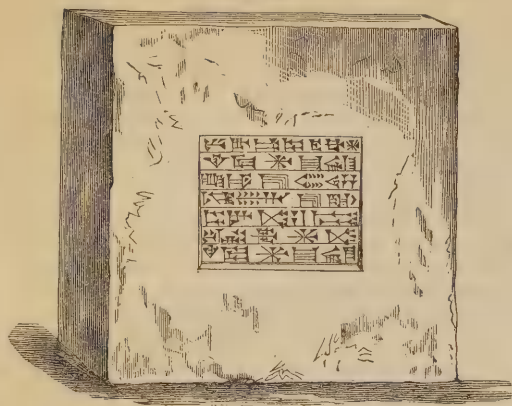

Both the Assyrians and the Babylonians used sun-dried bricks, as well as those that were baked in the furnace. The former were chiefly employed in the construction of the massive and lofty mounds upon which the more important edifices were constructed, the latter being substituted when more finished and careful brick-work was required. The kiln-baked bricks are generally of a pale-red hue, and they bear an inscription in the arrow-head character, which is impressed on the mass in true intaglio, and not obtained in a sunk bas-relief as in the Egyptian examples. In the Assyrian bricks the inscriptions cover one of the sides, or they sometimes run along the edge; but the Babylonian brick-makers stamped their inscriptions with moulds that covered only a comparatively small portion of the surface of each brick, somewhat after the Egyptian fashion. The inscription upon the specimen from Babylonia—Fig. 425—now preserved in the collection of the Royal Society of Literature, is read by Sir H. RAWLINSON as follows:—

(of) NEBUCHADNEZZAR,
the king of Babylon,
founder of Beth Digla, or Saggalu,
and of Beth Tzida,
son of NEBOPALASAR (I am).

Dr. HINCKS and Mr. LAYARD read *Beth Shaggah* in-

stead of *Beth Digla*. The rectangular bricks of Assyria vary in size from a square of twenty-two inches to one

Fig. 425.

of twelve inches, many of the varieties being elongated rectangles; their thickness also varies from four and a half to three inches. The Babylonian bricks are smaller, their maximum dimensions being a square of fourteen inches by four inches in thickness. Occasionally bricks of various shapes, and variously colored, are found throughout Mesopotamia.

The inscriptions that impart a peculiar value to the kiln-burnt bricks of Assyria consist of various formulæ, that have more or less direct reference to the edifice of which it was intended that they should form parts, together with the name, titles, and sometimes some steps in the genealogy of the reigning king. The formula upon each brick in a building was the same, with some unessential but very significant variations, such as the interchange of certain cuneiform equivalents. It is these variations, as BIRCH observes, that teach the secret of the language. The inscription on the bricks of the N.W., or oldest palace of Nimrud, which is in three lines, Sir H. RAWLINSON has read as follows:—

This is the palace of ASAR-ADEN PAL, powerful king, king of Assyria;
Son of ABED-BAR, king of Assyria;
Son of PUL, powerful king, king of Assyria.

By the Greeks sun-dried bricks were occasionally used for the construction of fortifications, since they were found to offer a more effectual resistance to the battering-ram than such as had been submitted to the action of the furnace. The walls of Mantinea afford a celebrated example. The same primitive and simple materials were also employed in the walls of the temples of the Leprean Demeter in Africa, and of the Stirian Demeter at Styros, and in those of the shrine of Æsculapius at Panopeus. Kiln-baked bricks, however, formed very commonly the walls of their less important buildings amongst the Greeks; and, in some instances, they may have been introduced by them into their nobler edifices. But Greece was a land abounding in stone, and the Greeks preferred the natural building material of their country to the productions of the kiln. Greek bricks were named from their dimensions

measured in palms—*didōron*, of two palms, or six inches in breadth, the length being one foot; *tetradōron*, of four palms, a square of one foot; and *pentadōron*, of five palms, a square of fifteen inches. In addition to these, with the view both to render their works more solid, and to improve their appearance, the Greeks occasionally made use of bricks of half the foregoing dimensions. VITRUVIUS describes another Greek brick under the title of *lydron*, which was six palms in length and four in width—that is, eighteen inches by twelve inches.

Bricks were used in profuse abundance by the Romans, both in the imperial city itself and throughout the empire. It was the boast of AUGUSTUS, indeed, that he had found a brick-built Rome, but that he left it a city of stone; from the time of TRAJAN, however, the ancient system of brick construction again became prevalent, and was never subsequently discontinued. The Romans frequently used their bricks in layers, alternately with masonry of rough stones, and they also as commonly constructed edifices of every description entirely with bricks. The clay of the Roman brick is remarkable for its hardness, and it generally has a fine red color. The baked bricks were designated *cocti* or *coctiles*, and the various sizes in constant use were further distinguished by the terms *bipedales* and *sesquipedales*, or two feet and eighteen inch bricks. Very minute particulars respecting the bricks of the Romans are given by both PLINY and VITRUVIUS, and the examples that are continually found in this country in considerable numbers fully corroborate the accuracy of their statements. The general sizes of the existing Romans bricks are seventeen by eleven inches, and fifteen by fourteen inches, the prevalent thickness being about two inches. Upon some of the earlier Roman bricks, the names of the consuls who were in office at the time of their fabrication may still be traced. The inscriptions stamped upon other specimens proved that the wealthy Romans of the imperial city derived no unimportant portions of their revenues from these, the simplest of fictile manufactures. The largest number of Roman bricks—or, possibly, of bricks that may have been made by Anglo-Saxon potters after the Roman fashion—that is now known to exist and to be in use in any one spot in England, may be seen forming parts of that most venerable and interesting edifice, the abbey church of St. Alban.

TILES.—In addition to the large bricks, whether sun-dried or furnace-baked, that were made for constructive uses of whatsoever kind, the ancients also manufactured vast quantities of thin tiles, of various sizes, and employed them for a multiplicity of useful purposes. Roofing-tiles were made much after the manner of similar appliances at the present time. Small flat tiles, and large ones also, were in habitual use for inlaying. Wall surfaces were variously decorated by this process, which was also applied to the adornment of door-jambs and other similar parts of buildings. Still smaller tiles, or tesserae, produced the inlaid or tessellated pavements that are so happily characteristic of ancient architecture. For all these purposes the tiles employed were formed in the East of a paste or body that would readily receive the glazing, with which in those regions their

surfaces were uniformly covered. The glazed tiles of the Egyptians, of which examples remain of a period as early as that of the sixth dynasty, were composed of a sandy friable compound, containing but little true clay, and exhibiting in different specimens considerable variety in the proportions and sometimes in the nature of its constituents, according to the manufactory or the period of production. This comparatively impracticable material was employed by the Egyptian potters because their silicious glaze—the use of lead in glazing not having yet been discovered—required to be applied to fabrics also silicious, and in which the sand was held in a granular condition—a result that was effected in the tile-body by the clay. The glaze itself, apparently formed of pulverized silica and soda, obtained its colors from the admixture of metallic oxides. An oxide of copper produced the well-known and deservedly famous Egyptian celestial-blue glaze that still retains its lustre untarnished, and will endure a comparison with the finest productions of modern science. The green glaze is of a kindred nature with the blue; and manganese, gold, silver, tin, and probably the suboxide of copper were the agents that produced the violet, yellow, white, and red hues. Of these colors, the blue is the one that is pre-eminently characteristic of the potters of Egypt.

The Assyrians applied a glaze or enamel to some of their kiln-dried bricks, on one face only, which was also enriched with various architectural devices, and so they provided themselves with substitutes for inlaying-tiles. The colors used by them were blue, yellow, white, red, and black. The specimens that remain are comparatively few in number, and in both their enamel and their hues they have lost much of their original effectiveness. That the Babylonians adopted a similar usage, is attested by the fragments of glazed ware that are scattered throughout the ruins of ancient Chaldea. By the Eastern nations of antiquity tiles of another class were in constant use for the reception of inscriptions, and in very many instances they were made to discharge the duties now assigned to writing-paper. The Assyrians were the great writers upon tiles, and they also employed cylinders and prisms for the same purpose. Documents of every conceivable variety were engraven on these singular but imperishable tablets, and the writing itself was executed with a minuteness, as well as a delicacy and precision, that are truly extraordinary. Many of these fictile records are of simple terra-cotta of the finest quality, while others are coated with a vitreous enamel. After the ancient national spirit of Egypt had in a great measure passed away with the departure of Egyptian independence, the papyrus often yielded on the banks of the Nile to terra-cotta, as the material for writing. Egyptian inscriptions on tiles, however, differ from the Assyrian in this important quality—that they were written in the ordinary black ink with a reed, and not incised with a sharp graving instrument before the tile was placed in the furnace.

Tiles were extensively used by the Greeks, both for roofing and for the flues of baths, and also in the construction of many of their tombs. The roofing-tiles are of large size, flat, and square, sometimes with flanges, and they have semicylindrical imbrices or rain-tiles to

cover their lines of junction. Two of the flat tiles in the British Museum measure two feet three inches, by eight inches. Many of these tiles are variously stamped with brief inscriptions in oblong labels. The imbrices are without inscriptions, but have painted ornaments. Another variety of Greek roofing-tiles were placed on the ends of the flat tiles for the purpose of additional security; these tiles, which are very ingeniously adapted for the duties required from them, are sometimes found to have been inscribed. The sepulchral tiles are of two kinds: those of the first variety are flat, and they were used to form a floor on which the remains of the deceased were placed; the other tiles are curved for the purpose of forming an arched covering. Drain-tiles, as well as those used for flues, were made by the Greeks of terra-cotta, and it is highly probable that they both employed the same material in the formation of the hollow floors of their own hypocausts, and transmitted that application of it to the Romans. The well-known *Keramicus*, as its name significantly declares, was a quarter of Athens almost exclusively devoted to the manufacture of bricks and tiles. Bricks and tiles were but rarely in use amongst the Etruscans; and the latter, when employed by that remarkable people, were apparently for the most part restricted to sepulchral purposes. Some late tiles of this class have been discovered, which are impressed with brief commemorative legends; and a single instance has been recorded of an Etruscan monumental tile, upon which the figure of the deceased had been incised, somewhat after a mediæval fashion, in addition to the customary inscription.

By the Romans tiles were used in great abundance, and they were adapted to various requirements. Roman tiles are found in much greater quantities than bricks, so much so, indeed, that it is by no means uncommon to apply the one term—Roman tiles—as well to the bricks as to the tiles themselves. The Latin equivalent for this word tile—*tegula*—is derived from the verb *tegere*—to cover—which expresses the primary application of Roman tiles. Thus ISIDORUS writes, *Tegula, quod ædes tegat*—a tegula or tile—because it covers houses; and he adds, *Imbrex, quod accipiat imbres*—an imbrex, or curved joint-tile—because it receives, that is, *wards off*, the showers. The tile-makers were distinguished by the title of *Tegularii*. Roman tiles closely resemble the bricks in their composition and mode of production, but their paste is generally somewhat inferior in quality, and the tile is always much thinner than the brick in proportion to its superficial extent. The flat roofing tiles, in common with those devoted to other uses, have inscriptions stamped upon them, their own special characteristic being their flanges. These flanged tiles were used for roofing both public and private edifices, for hypocausts, and for pavements, and numerous instances occur in which they appear banded into the Roman wall masonry. The flanges of two adjacent tiles, which generally rise two and a quarter inches above their flat faces, were covered by an imbrex set inverted over them, and by a repetition of this process the required roofing was completed. The end-tiles are found to have been suitably modified in form and adjusted to their office; the existing specimens are provided with spouts, and decorated either with the

brush or in relief. Some roofing-tiles, however, were made quite flat, and were hung, lozenge-wise, from one corner, overlapping one another like scales, or like feathers, as the Romans evidently preferred to draw the similitude, since they designated this style of tile-roof *peacock-work, opus pavonacum*.

Flue-tiles, which are necessarily hollow, almost invariably measure sixteen and a half inches in length, by six and a half inches in width and five in depth. They have their surfaces scored either with wavy lines or more systematic patterns.

Drain-tiles, or terra-cotta pipes, are larger than those used for flues, and they were formed in a manner consistent with their object.

Wall-tiles, employed by the Romans for casing interior wall surfaces, are large thin squares of terra-cotta, and they generally were decorated on one side with incised figures and patterns.

The small paving-tiles, so well known as *tesserae* and *tessellæ*—the latter term a diminutive of the former—the components of *tessellated pavements*, declare their square form under their title, which is evidently derived from the Greek *τεσσαρες*—*tessares*—*four*. They were made by cutting larger tiles into small cubes, or else they were formed in the first instance in distinct moulds. They vary in size from about an inch to a quarter of an inch square. The red portions of the mosaic work of pavements were produced by these small terra-cotta cubes, which were also used, though less frequently, in the formation of Roman mosaics for other purposes. It may be observed, that of the Roman tessellated pavements now known to be in existence none are earlier than the Augustan age, while the greater number date from the succeeding century.

There remains to be noticed one other distinctive application of their large flat tiles by the Romans, which is their use of them both in the formation of their graves and for preserving their commemorative monumental inscriptions. In close conformity with the Greek usage, some tiles laid flat formed the flooring upon which the body might rest, and others set sloping in opposite directions provided a simple ridged covering to protect it from the superincumbent earth. The vases that contain burnt bones are sometimes found to have been protected in a similar manner. The inscribed tiles, having their Greek or Latin legend generally written across them from side to side, were placed very much in the same manner as modern gravestones.

The inscriptions that are preserved upon the various tiles that have come down from the Roman times, abound in highly interesting as well as very valuable information. Considerable numbers are inscribed with the names or initials of the consuls of the year when particular specimens were manufactured. Still larger numbers set forth the names of the potteries and of the estates, with their proprietors, from which the clay was procured and where the tiles were made, together with notices of the manufacturers, and various brief descriptive or auspicious sentences and mottoes. The consular tiles, as they may be distinguished, are found only in Italy; they appear to have been thus stamped, in conformity with some law of about the time of TRAJAN, as a guarantee of the quality of the

clay used in the fabrication of them. Large collections of these tiles, obtained from almost every great edifice of ancient Rome, are still in existence, and many are yet in use upon the roofs of the churches of the modern city. The tile-inscription, whatever its character, was produced from a stamp or die in a low sunk relief, the raised letters being on a level with the face of the tile itself. In the centre of the circular composition upon a tile now in the British Museum, is a small medallion formed of a figure of victory, which was the mark of the potter; this is encircled by two bands of letters; those of the outer band are larger than the others, and with them the inscription commences. It may be read thus:—*OPUS DOL (IARE) DE FIGUL (INIS) PUBLIANIS (EX) PREDI AEMILIAES SEVERAES*—*Pottery from the Publian potteries, from the estate of Emilia Severa*. This, though a characteristic, is by no means a perfect specimen of these remarkable inscriptions. As a matter of course, in other specimens, the productions of different establishments and various makers, the central devices exhibit a variety of characters; they are not very numerous, however, and sometimes they are altogether omitted. The most complete stamps, says BRICH, have the date of the emperor or of the consulship, the name of the estate which supplied the clay, that of the pottery which baked it, and of the potter who prepared it, sometimes even of the slave who moulded the tile, and the very dimensions of the tile itself. In a few instances also the tiles have inscriptions, indicating the places where they were to be used. The greater number of these appear to have been directly associated with the Roman soldiery, by whom in many instances they were made, and in whose quarters, camps, and places of interment they were applied to their destined uses. These relics have served to trace out the stations of various legions, and even their line of march from station to station. In some instances the tiles specify, not a particular legion only, but certain cohorts of those legions. The numbers and the titles of the legions are given in these singularly interesting inscriptions, as *the Second, August; the Sixth, Victorious, Pious, and Fortunate*. The letters are always sharply expressed, as if from well cut metallic dies, and they are more generally arranged in the form of a foot than of a circle. The route of the twenty-second legion has been traced through Germany by the tiles that lingered at its successive stations; and in this country these tiles have declared what legions they were that occupied quarters at places most distinguished in Roman Britain. Thus the tiles of the sixth and ninth legions have been found at York; those of the twentieth, Valerian and Victorious, at Chester; and others of the second, at the ancient Isca Silurum, or Caerleon.

CHINESE CERAMIC MANUFACTURES.—It is not known whether there have been preserved amongst the Chinese any specimens either of terra-cotta or of glazed pottery of a date earlier than the great tower of Nankin, which was completed in 1431, after nineteen years' work; several similar edifices having been successively erected and destroyed upon the same site. It consists of nine stories in height, and is constructed

entirely of glazed tiles and slabs of earthenware. At the present day the manufacture of common pottery is carried on to a great extent in China. Some vessels of this class, of very large size, are employed by wealthy Chinese as reservoirs for gold fish and aquatic plants, or for containing and storing up fruits and grain, and for other like purposes; but the smaller productions of the terra-cotta potteries of China, which are greatly encouraged by the government, are almost exclusively devoted to providing for the requirements of the humbler classes of the vast population. As an article of export, the common opaque pottery of China has been completely set aside by the beautiful and universally admired ware, distinguished by the title of PORCELAIN, which is formed from a fine and hard paste, possessing the peculiar quality of being *translucid*. Thus porcelain occupies a position midway between pottery and glass. It is presumed to be of Chinese origin, and it certainly was known and extensively manufactured in China from a very early period. The Chinese, indeed, claim for their ceramic manufactures the same far-extending antiquity that they assign to the history of their extraordinary empire. The isolation, however, which it has been the policy of the natives of China to maintain during so many ages, coupled with the guarded secrecy that so generally has enveloped their manufacturing processes until very recently, has precluded the possibility of national intercourse, and rendered hopeless the attainment of any credible and satisfactory information relative to the rise and progress of a particular industry in that country.

The first European who is recorded to have penetrated into China, and to have explored Chinese productions on their own soil, was the Venetian, MARCO POLO. Writing in the thirteenth century, this famous traveller alludes to the extent and importance of the porcelain manufactures in the Celestial Empire, and he states of one place, Kinsai, that there was nothing further to be observed, than that cups or bowls and dishes of porcelain wares were there manufactured. MARCO POLO returned to Venice in the year 1295, and died there in 1323. It seems to be highly probable that Chinese porcelain had been exported in considerable quantities to other Eastern countries, many centuries before it was seen in China by MARCO POLO. Thus mention is made of a service consisting of forty pieces having been sent in 1171 to NOUREDDIN, the caliph of Syria, by his lieutenant, SALADIN, who afterwards became the hero of the crusades. This present may be considered to have travelled by way of Egypt, into which country and into Persia there can be no doubt of porcelain having been introduced direct from China, at a very early period, as an article of commerce. In 1474 the Venetian ambassador at the court of Persia considered it to be his duty to submit to his government a special communication upon the subject of this art-manufacture. Fifteen years later, amongst other rare and costly presents, an ambassador from the sultan of Egypt brought to LORENZO DI MEDICI some large vases of Chinese porcelain—*vassi grandi di porcellana*. Early in the following century the Portuguese, who were the first adventurers that doubled the Cape, imported the finest wares of the East, in large

quantities, into Europe, and from that period the different European nations gradually became familiarized with porcelain. CAVENDISH, the celebrated traveller in the time of Queen ELIZABETH, is generally supposed to have presented to his royal mistress the first pieces of oriental porcelain that came into England; but it has been also considered, that a few specimens of this precious ware had found their way to these shores as early as the commencement of the sixteenth century. Archbishop WAREHAM's silver-mounted bowl of the pale green thick porcelain, preserved at New College, Oxford, is one of the earliest specimens known now to be in existence in this country. In the year 1600 the English East India Company was formed, but it did not succeed in establishing a regular importation of *china* until after it had been for thirty years in operation.

From the earliest period the Chinese have systematically refused to export the finest, richest, and most valuable of their porcelain, except in very rare instances. It has also been their uniform practice to keep the composition of this manufacture a profound secret; and accordingly they have always endeavored to mislead all inquiring strangers, with the most marvellous tales respecting the nature and the preparation of the materials. Thus MARCO POLO has recorded that the Chinese collect a certain kind of earth, as it were, from a mine, and laying it in a great heap, suffer it to be exposed to the wind, rain, and sun for thirty or forty years, during which time it is never disturbed. By this means it becomes refined and fit for being wrought into the vessels above mentioned. Such colors as may be thought proper are then laid on, and the ware is afterwards baked in ovens or furnaces. Those persons, therefore, who cause the earth to be dug, collect it for their children and grandchildren.

Other early writers have stated that the porcelain-composition is formed from marine shells, egg shells, gypsum, and other strange substances, which are tempered and thickened, in order to their being adapted to their future application, by being buried in the earth for eighty or one hundred years. Hence Dr. JOHNSON's fanciful derivation of the term porcelain itself—*pour cent années*. Lord BACON entertained the idea that there were strata or beds of the porcelain-clays in China which, being buried beneath the surface of the ground, by length of time became congealed and glazed into that fine substance which afterwards produced the China wares. At length some light was thrown upon the subject by the French Jesuit missionary, D'ENTRECOLLES, who learned many particulars respecting the production of porcelain, both from his converts and from Chinese books upon the subject, and was permitted in person to witness the actual processes of the manufacture. He fully detailed all the particulars in a letter, dated Jao-tcheou, September 1, 1712, which, together with specimens of the two principal materials, he transmitted to Paris. These specimens formed the basis of a series of experiments by RÉAUMUR that ultimately led, when the proper materials had been discovered in France, to the production of the fine porcelain of Sévres.

The high antiquity of the art of making porcelain, and the perfection to which it had attained amongst the Chinese long before any specimens had reached Europe, had for many years been well-authenticated facts, before any definite and precise information had been obtained from records preserved amongst the Chinese themselves. This equally valuable and interesting source of information was reserved for M. STANISLAUS JULIEN, the eminent Chinese scholar, to lay open before us in his translation of a work upon the history of the porcelain of King-te-Tchin, published by him at Paris in 1856, with an elaborate preface and notes obtained from the writings of various Chinese authors. Having referred to the remarkable circumstance, that the Chinese possess an exact chronology from the most remote antiquity to the present time, M. JULIEN states that their official annals record the Emperor HOANG-TI to have been the inventor of pottery, two thousand seven hundred years before the Christian era. Porcelain, the same chroniclers declare to have been first fabricated under the HAN dynasty, who flourished about 185 before CHRIST, thus claiming for the discovery of porcelain an antiquity approaching to two thousand years, and a priority of at least one thousand six hundred years over the first manufacture of this ware in Europe. After sketching out the progressive development of the porcelain manufacture under different dynasties, M. JULIEN proceeds to enumerate fifty-six establishments for its production; after which he describes minutely the great manufactory of King-te-Tchin, that for more than eight centuries has enjoyed the especial patronage of the Chinese emperors. Three thousand furnaces are now in constant operation at King-te-Tchin, which may be said to send their productions to the whole world. Their works may be grouped in two great classes—the one consisting of imitations of the ancient porcelains of the empire, and the other comprising new varieties of both form and color. Amongst the porcelains held in the highest esteem in China, as well as by Europeans, and which were made at early periods, are the celebrated *crackle* vases that are covered with a minute and delicate network of fine surface cracks, produced during the process of manufacture by plunging the heated porcelain in cold water, or by mixing stearite with the glaze. The cracks having been filled up with some thick, colored composition, or with a flux that has been tintured ruby-red by dissolved gold, the porcelain receives its finish. The *egg-shell* is another early porcelain in the highest repute. Its texture is so slight and delicate as to be almost transparent, and yet jars and vases of considerable size were made of it, as well as cups, plates, and other smaller objects. It attained to its highest perfection during the second half of the fifteenth century of this era, when it was fabricated as thin as *bamboo paper*. Some of the finest examples of this porcelain are of a pure white; in others the glaze is creamy, and minutely granulated; and many others are painted chiefly with a cobalt-blue of exquisite beauty. The true cobalt became exhausted in China about 1500, when foreign cobalt was for the first time introduced into the Chinese ceramic manufactories. A native pigment,

found in abundance in all the provinces of the empire, and which is presumed to be a cobaltiferous manganese, is still used by the Chinese artists, who now obtain their true cobalt from England.

Not the least remarkable portions of M. JULIEN's work are those which describe the practice of making, at King-te-tchin, an inferior species of porcelain for the express purpose of exportation, and which also direct attention to the fraudulent and deceptive practices of Chinese porcelain dealers in their transactions with foreign purchasers. Such impositions have not restricted their sphere of action even to the wide limits of the Chinese empire; nor are the inexperienced and unwary the only persons who have by these means been misled. In his highly interesting and most valuable work, *On the Manners and Customs of the Ancient Egyptians*, Sir GARDINER WILKINSON states that great curiosity and surprise were excited by the discovery in certain of the most ancient tombs at Thebes of small bottles of porcelain, unquestionably of Chinese manufacture, and bearing inscriptions in that language. These bottles are about two inches in height; one side of them is ornamented with a flower, and the other bears the legend. They are formed, not of very fine porcelain, but of such as might have been produced before the processes of the manufacture had attained to an advanced degree of perfection—a circumstance that was considered to corroborate their supposed production at a Pharaonic period, no less remote than that of the eighteenth dynasty—before CHRIST 1575 1289—in a tomb of which era one of the specimens was found by ROSELLINI. Subsequent investigations have proved that the characters of the writing upon these bottles were not introduced into China until about 40 before CHRIST, and also that the verses inscribed upon two of their number are to be found in the works of Chinese writers of the eighth century of this age. Similar bottles have since been purchased in China, where they are commonly used to contain snuff, medicines, and other articles of which small quantities only are required. These modern bottles have precisely the same inscriptions with those of the Theban tombs. Another of these bottles has been obtained at Khorsabad, and at Candy they have been seen exposed for sale in a large basket. Hence it is evident that they are exported at the present time from China, and would easily reach the Arabs of modern Egypt, by whom they were, in all probability, placed in the tombs for the deliberate purpose of deception. Such are the evidences that archæologists of this day adduce, before they accept the authenticity of a startling discovery; and, in this particular instance, it is in consequence of these results of careful inquiries that the learned writer upon Egyptian antiquities, who first noticed the little Chinese bottles, is quite prepared to abandon all notion of their antiquity. It has been suggested by MARRYAT that the small seals of pure white Chinese porcelain, highly vitrified, that have been dug up both in Cornwall and Ireland, may, in like manner, have been purposely deposited to try the assumed credulity of archæologists. These seals are all alike in form and size; the handle is formed of the figure of a monkey sitting upon an exact cube rather more than half an inch

square, and on the bottom of this cube is engraved the motto of the seal. It does not appear that such seals are now made in China, though it is quite possible that they may yet be discovered there in abundance. However they may have found their way, either to Cornwall or to the depths of an Irish bog, this one thing is certain—that, by some means, there they have been seen.

While the history of the porcelain manufactures of China to a certain extent has been laid open through the intelligent perseverance of M. JULIEN, all reference to the primitive operations of the Chinese ceramists still continues to be raised but little above

conjecture and speculation. When seeking to trace the progressive outline of the history of the ceramic art, it, accordingly, becomes necessary to have recourse to the accredited traditions of Egypt, Assyria, and Greece.

EGYPTIAN POTTERY.—The memory of the earliest miscellaneous pottery of Egypt has been preserved through the instrumentality of hieroglyphics, which commence from the remote era of the third and fourth dynasties, before CHRIST 3000-2000, and represent various kinds of fictile vessels, the earliest of a red earthenware, in use for the ordinary purposes of domestic life. A succession of these curious sepulchral pictures enables

Fig. 428.

Fig. 427.

Fig. 426.

one to trace the progress of the potter's art amongst the ancient Egyptians, and its practice also, from the almost primæval period of the third dynasty, until the power of Rome had extended its influence along the valley of the Nile. Vessels of every variety of form, size, and application are thus represented; and by the same means mankind is rendered familiar with the simple manufacturing processes prevalent amongst the potters

of Egypt. In the tombs that the living Egyptians prepared with such sedulous care for their own final rest, and which they delighted to fill with graphic pictures of Egyptian life, the clay is seen in the act of preparation, and the artificers at work upon it; and close at hand are the furnaces in which their productions were to be baked. The wall-paintings of the tombs excavated at Beni-Hassan while the sovereigns

Fig. 429.

Fig. 430.

of the twelfth dynasty were in power, have supplied illustrative examples—Figs. 426, 427, 428, 429, and 430. After the clay had been dug up, it was prepared by kneading with the feet—a process denominated *hi hat*—Fig. 426. The clay in this state was divided into suitable masses by the workmen—Fig. 427—and carried by them—Fig. 428—to be wrought on the wheel or by the lathe. The wheel is represented twice in Fig. 429; it was a flat table, circular or hexagonal in form, and it appears to have been turned with the left hand, whilst the right was engaged in forming the

required vessel. The various objects, when formed, were placed in a blast furnace, cylindrical in shape, from the head of which the flames issued forth—Fig. 430.

With the advance of civilization, the potters of Egypt very considerably extended the range of their operations, and introduced into their various productions many important improvements. Egyptian pottery, however, does not appear at any time or under any circumstances to have aimed at a high art-character. It was a manufacture designed for purposes of practical utility, and its decorations were held to be altogether

subordinate to its usefulness. At the same time, the Egyptian potters were by no means destitute of some sense of the beautiful, both in form and in adornment, though in their most perfect works they fall far short of the artistic excellence generally prevalent in the fictile productions of the Greeks. True Egyptian vases may be said to be distinguished by the absence of a high mechanical finish, by the prevalence of forms which are evidently imitations of well-known fruits and flowers, by their pointed bases, and by the extreme smallness of their necks and orifices. There are also certain peculiar national conventionalisms of style and treatment, that impart a peculiar Egyptian character to the pottery of Egypt so long as the country itself maintained its own independence. Subsequently, after the substitution of Greek and Roman power for that of Egypt herself, the pottery of the Egyptians in many respects became assimilated with the cognate productions of Greece and Rome. It must be added that the more artistic of the ceramic works of the Egyptians exist in comparatively small numbers, while in the greater proportion of them the simplicity of their character scarcely rises above rudeness. The most important feature in early Egyptian pottery consists in their hieroglyphic legends, which very greatly enhance the value of the relics themselves, since they enable students to determine the age of specimens that are identical, both in their composition and in their type and ornaments, and to assign them their proper places in the history of Egyptian art.

In addition to their bricks, the Egyptians manufactured various objects in clay, which they considered capable of receiving a sufficient degree of hardness from the action of the sun. The perishable nature of such wares has not permitted many objects of this class to remain. The few that have been preserved are of a late date, and they almost exclusively consist of the small figures so commonly used in Egypt as votive offerings, together with various decorations for the interior of tombs. These relics were evidently fabricated in imitation of more valuable and costly works, for which they may have been originally substituted; or they may, in the first instance, have been designed to provide for the requirements of such as could not obtain fictile productions of a higher order.

The earliest and simplest pottery that the Egyptians placed in the furnace to be baked by an artificial heat, was formed from the ordinary unctuous and plastic clay which is regularly deposited by the inundations of the Nile. The earthenware thus produced is coarse and porous, without polish, and of a dull dark-red color, externally tinged with a purple hue, or inclining to a reddish-yellow when the action of the fire had been but comparatively successful. Improvements were gradually introduced into the paste of their terra-cotta by the Egyptian potters; and their manufacturing processes also, in course of time, underwent such modifications as enabled them successfully to undertake the production of an almost infinite variety of objects. The great majority of these works may be included under the comprehensive title of *Vases*—vessels varying in dimensions from being several feet in height, to being scarcely a single inch, and of corresponding circum-

ferences; and adapted, in their diversified forms, to the special requirements of every imaginable use. Those destined to contain liquids are of a jar shape. The Nile water, intended for oblations, was placed in others that are tall and thin, with a spout. Bread, roast meats, and water fowl were placed, says BIRCH, in deep dishes. Oils and drugs were kept in tall conical jars, carefully covered and tied down—ointments, salves, and extracts, in small pots. Other cosmetics were held in a jug with a spout; wine, honey, and other liquids were deposited in open-mouthed jars, out of which they could readily be drawn. Almost every purpose to which jars and other vessels of pottery, together with baskets and vessels formed of the common metals, are put in this country, was discharged by some species of terra-cotta vase, in the case of the ancient Egyptians. In vases of different kinds water was raised from the Nile and distributed by the water-carriers, and conveyed to the lips of both men and animals. Other vases were used in making and storing wine, in bringing it out for use, and in drinking it. The butcher, the poulterer, and the cook, had each their own vases, in which they disposed of their viands. Even the weaver used terra-cotta vessels to hold his flax, and reeled it out of them. Jars held the colors of the artist, and the cements of the plasterer. The grains of corn, before they had been pounded in the mortar, and the flour after it had been thus produced, were kept in vases. Vases held the embalmer's bitumen, and the water used by the scribes. Vases also provided the hod of the laborer, the smelter's bucket and crucible, the jar of the cow-doctor, and the pail of the milk-man.

The pots which contained and preserved the mummies of the sacred ibis at Memphis were formed of a coarse red pottery, or, in some instances, of a finer glazed ware. Similar vessels were also used as receptacles for the mummies of certain sacred animals. Sepulchral vases of various forms were employed in their interments, by the humbler Egyptians, for receiving the intestines, after they had been removed from the bodies and had been embalmed. The *shabti*, or sepulchral figures, which were deposited with the mummies, and formed a part of the funeral relics, were made of terra-cotta, and, in some few instances, of sun-dried clay. The models of coffins or mummy cases, which HERODOTUS records to have been shown by the Egyptian undertakers to the relatives of the deceased, were produced in terra-cotta. The sepulchral cones, again, that were introduced for the purpose of decoration into the interior of the Egyptian sepulchres, were of the same material. These singular objects, that have excited so much curiosity, and caused such diversified speculations, vary from six to twelve inches in length, and are about three inches in diameter at their base. They bear stamped inscriptions, always of a funereal character, and, in almost every instance, stating the name of the person to be commemorated, and conveying some personal information respecting him. Figures and scenes, also, of a sepulchral import, are occasionally introduced instead of inscriptions. The inscriptions upon these cones contribute, in no slight degree, to elucidate the interior organization of

ancient Egypt, and to illustrate its political and social condition, by setting forth a long list of public functionaries with their relative degrees of precedence. As the eye ranges over these tickets of the dead, remarks BIRCH, one is forcibly reminded of the visiting cards of the living. Sacred scribes, royal officers and secretaries, clerks and accountants, priests, viceroys, counsellors, seal-bearers, scribes of the treasury and of the granaries, chamberlains, prefects, incense-bearers—all of them tenants of the sepulchres of the ancient No-ammon or Diospolis, and of still more ancient Noph or Memphis, seem to have left these relics behind them as if to make a call on posterity. Recent discoveries at Warka in Babylonia have proved that these cones were used as bricks, in the formation of the interior walls of the sepulchres, where they were arranged in patterns, their inscribed bases being outwards.

In addition to their varieties of form and size, the vases of the Egyptians may be distinguished by their having either two or more handles, or a single handle, or by their being altogether unprovided with any such appendage. The British Museum contains many highly interesting specimens of each class. The similarity that is so evident between these vases and the painted representations of them that frequently occur in the hieroglyphics, corroborates, in the most satisfactory manner, the descriptive fidelity, and consequently the historical truthfulness of the Egyptian picture-writings. This pottery of Egypt also most clearly indicates that, while it retains certain qualities peculiar to itself, it is the evident prototype of the more beautiful ceramic productions of the Greeks.

Amongst the objects made from baked clay in Egypt during the era of the Roman dominion, are lamps that bear a close resemblance to the terra-cotta lamps of Roman Italy; they take but a low rank, however, as works of art. Lamps of early date, and of higher artistic qualities, have not been preserved in Egypt.

Polished Egyptian Pottery.—The smaller and finer productions of the Egyptian potters, and such as were destined for uses immediately connected with the refinements of life, were either polished by a mechanical process, or covered with a vitreous glaze, so thin as to escape detection. Different clays were employed in the production of the polished vessels that were adapted to various uses; a distinct and beautiful variety is of a uniformly rich red color throughout, which was evidently held in high esteem by the Egyptians themselves. Many of the existing specimens are elegant in their design, and modelled with much skill. This ware, however, notwithstanding its merit, is inferior to the red pottery of the Romans; at the same time, it undoubtedly possesses the required property of cooling liquids poured into it. According to BRONGNIART, the analysis of the polished red ware is—

	Centesimally.
Silica,	56.13
Alumina,	18.54
Oxide of iron and manganese,	9.00
Carbonate of lime,	5.24
Manganese,	1.07
Water,	5.56
Carbonic acid,	4.46

100.00

Some vessels of this ware have been found in the tombs at Thebes. Other varieties are formed from a brown or a black paste—in the others again, the paste is of a light-red tint. A white chalk coating generally covers the vessels and other objects of these classes, which may be considered generally to have been made in imitation of similar objects in more precious materials. Amongst the more characteristic specimens of this polished ware that remain, are small cruses or *lecythi*, for containing liquids, of which small quantities only were required. Some of these *lecythi* are double, and have their globular bodies and tall necks united by a narrow band of the terra-cotta. Other examples have oval bodies, narrow necks, and pointed bases; another kind of jug has a compressed body and wide open mouth, and sometimes it appears with two handles; again, other vessels are egg-shaped, while in some human and animal forms are introduced.

To this same class of polished pottery belong the vases that were made in Egypt after the subjugation of the country by ALEXANDER the Great, and which have been distinguished by the title of Græco-Egyptian. The texture of this pottery is comparatively fine and homogeneous, though, in some examples, it is very coarse and mixed up with white or grey particles of a stony nature. In color, different specimens vary from a deep to a pale tint of red or grey. Vases of various forms, and large bowl-like jars, are the principal works of this class that have been found; and they are adorned with figures, flowers, architectural devices and patterns, that are painted in black or red upon the clay.

Glazed Egyptian Pottery.—The substance already described as having been used in the production of their highly glazed tiles, was also commonly employed by the Egyptians for fabricating a vast number of other objects, all of them peculiarly characteristic of their makers. To this glazed pottery of Egypt the term *Porcelain* has very generally been applied: but this use of the word is altogether incorrect, since the glazed fictile works of the Egyptians possess neither the hardness, the compactness, nor the translucence of that peculiar class of ceramic productions. The nature of the material that, in this glazed pottery, was substituted for potter's clay, also distinguishes it from what might be appropriately styled glazed terra-cotta. The constituent parts of this pottery have been found to consist of silica, alumina, carbonate of lime, magnesia, and water; but it does not appear that these substances were combined in any definite or fixed proportions. Whatever amount of clay was incorporated with the compound, was evidently employed for the purpose of holding together the arenaceous portions of the mass; and on the other hand, the presence of the sand was necessary in order to secure the adhesion of the silicious glaze or enamel, which, with its coloring obtained from metallic oxides, was to cover the surface of every object. This peculiar and very beautiful ware was both extensively used in Egypt, and also considered to be of sufficient value to be imported into foreign countries; as is proved by the circumstance, that objects formed of it have been discovered in Greece and Italy. In Egypt this ware was manufactured as early as the sixth dynasty.

The vases made of glazed pottery are of small size, few of them being more than twelve inches in height; and such vases as were produced in this manner, were evidently designed rather for decorative than for useful purposes. They vary in form and in their style of adornment, many of them being evidently modelled in imitation of similar productions in the precious metals. Examples have been observed that are inlaid with a compound of a different color from the body of the vase. Inscriptions occur amongst the devices and patterns introduced into these works by the Egyptian potters; and it is worthy of particular notice that an Assyrian style of art is apparent in some specimens of the glazed

Fig. 431.

pottery, themselves undoubtedly of Egyptian production, that have been discovered amongst the relics of ancient Egypt.

In addition to the *shabti* or *shabshab* of terra-cotta, the same kind of sepulchral figures were made in great abundance in Egypt, of the brightly-colored glazed pottery. So numerous, indeed, are these singular relics, that the production of them must have constituted a staple manufacture in the potteries of ancient Egypt. Known to have been used only in Egypt, where they were universally employed by persons of all ranks in their burial ceremonies, the *shabti*—Fig. 431—which vary in height from about a single inch to about nine or ten inches, may be supposed to represent, and to have been substituted for, the human victims that at one time were sacrificed at the funerals of the great and wealthy. It appears from the formula inscribed upon the *shabti* themselves,

that the use of these figures was to aid the deceased in his labors of preparing and irrigating the ground, and raising the crop in the mystical fields of the Aaheura, or Aahlu, probably the bean-fields of the Egyptian Elysium, and in the transport of the food from the west to the east.—*Birch*.

In addition to this formula from the sixth chapter of the Great Ritual of the Egyptians, the inscriptions upon the *shabti* generally set forth in hieroglyphics the name, style, and titles of the deceased; and they are arranged in horizontal lines down the front of the figure, and in perpendicular ones upon its back. Some of the figures are found to have been executed with the utmost care, and with no common skill. The inscriptions are either incised or produced in intaglio from a stamp, or sometimes they are merely written upon the surface of the glazed ware. Examples have been noticed which had been made ready for sale, having the formula inscribed

upon them, and with blanks left to be filled up with such names and titles as might be required. The *shabti* are generally repetitions of the same type, which represents the deceased as swathed in bandages, after the manner of a mummy set upright, the head and hands alone being exposed to the view. The head has a peculiar covering, with pendent ends. From the chin depends the beard, apparently inclosed in a beard-case; in the right hand is a pickaxe, while the left hand holds a hoe and a cord, to which, and hanging over the shoulder, there is attached a basket containing the seed-corn. The figure stands on a plinth, and sometimes at the back there is a small slab for the purpose, as it would seem, of attaching it to the wall of the tomb. At the era of the eighteenth and nineteenth dynasties, *shabti* of a different and rarer type prevailed. They represented the deceased as standing, and habited in the costume of the period. The prevalent color is the bright Egyptian celestial-blue; but some *shabti* are of a dark blue or purple hue, and a few others have been observed that are either green or brown.

The same material was also employed by the ancient Egyptian potters for the manufacture of innumerable small figures, and other objects, to be worn as amulets by both the dead and the living, together with bugles and beads of various sizes and forms, for which there once existed a demand so great, that they yet remain in prodigious numbers. The amulets comprise statuettes, on a diminutive scale, of the deities of the Egyptian Pantheon, with the sacred animals, and their various emblematic insignia; and they were adjusted to the requirements of the wearers, by being made in the form of pendants, studs, ear-drops, fibulæ, and rings. Concentric rows also were strung together, which would produce necklaces, bracelets, and anklets. Vast quantities of beads and bugles were used in forming the decorative or mystic network, so commonly placed about the mummies of the dead, and associated with amulets. The more elaborate of the beads that were applied to this singular use, were made in the form of different fruits and flowers, instead of having the spherical, globular, cylindrical, or annular forms more generally prevalent. In addition to the beaded-work, mummies have a pectoral ornament, also of enamelled pottery, which is almost universally in the form of an Egyptian pylon or doorway, and is decorated with different symbolical groups and figures, all of them having some sepulchral import. There yet remains to be noticed another class of sepulchral ornaments, of a kindred nature with the beads and bugles and amulets that cover the external bandages of the embalmed dead of ancient Egypt. These are the various other amulets and beads, which were evidently made for the express purpose of being suspended about the necks of the mummies. The figures introduced into these objects appear to have been selected upon some definite principle, and in conformity with a fixed rule; and they comprehend almost every mystic form or device that the Egyptians were wont to associate with the interment of their dead, and which were ordered to be placed upon certain parts of the body of the deceased, for the purpose either of conferring blessings or of averting evil. Finger-rings—*tebu*—formed

entirely of enamelled pottery, and adorned with characteristic and appropriate devices, were common in Egypt, and it is probable that they were used as well for sepulchral purposes as for the personal decoration of living Egyptians. Many of these relics that yet exist, are impressed with the names of well-known Egyptian kings, a circumstance that leads to the inference that these rings were worn, either in life or death, by personages of exalted rank, since the use of the king's name seems to have been restricted to functionaries of state—as the royal arms appear in England to have been introduced, in the middle ages, only into the monumental heraldry of those who had formerly held offices either immediately under the crown, or about the person of the sovereign.

The enamelled rings of Egypt, like the beads and statuettes and other decorative objects, were much prized by the Greeks and Etruscans. They have been found in the sepulchres of Etruria in settings of the exquisite gold filagree-work of the Etruscans, intermixed with precious stones and beads of gold, precisely as one would now testify admiration for the small cameo gems of WEDGEWOOD. In a tomb at the Polledrara near Vulci, in Italy, a heap of Egyptian beads and bugles was discovered, which had apparently formed a network covering, after the fashion of Egypt, to some bronze objects; but, the strings having yielded to the influence of time, the beads and bugles had fallen to the ground. Another tomb—one of those at Egyptian Thebes—contains a painted representation of the processes of finishing and stringing these simple and familiar objects. Three men are seen hard at work: one stands, and files bugles of green enamelled ware; a second is seated, with a basket full of these bugles before him, some of which he has arranged in a row for a necklace; and the third is drilling a hole in a piece of wood.

Their enamelled ware was employed by the Egyptians for the purpose of *inlaying* some of their figures, and for decorating their coffins by a similar process. In figures, when vitreous pastes were inlaid, says BIRCH, the portions made of this material were the extremities, as the fingers and toes, the beard and eyes, and parts of the dress, such as the collar round the neck, the bracelets, and anklets. One of the finest specimens of this application of the Egyptian enamelled ware in inlaying, adds the same able writer, is a head-dress or wig, found at Thebes, which formed part of a small figure of a king, probably about three feet high. The mass of which it is composed is of a deep-blue color, the fashionable head powder of the day being probably of that hue. So regular is the arrangement of the curls, that they appear to have been pressed out of a mould. A rich fillet or diadem, which passed round the head, is inlaid with small tesserae, about half an inch long and one-eighth of an inch wide, of bright-red paste, imitating jasper, and of gilded porcelain. In some instances the enamelled pottery is found to have been used with other substances, as ivory and various stones, for the purpose of inlaying. It was also applied to inlay a variety of domestic objects, some minutely small and others of a considerable size. The British Museum contains, besides other inlaid objects, a box of dark

wood, taken from a tomb at Thebes, that has on the lid and sides a square border formed of tesserae of blue enamelled pottery, alternating with similar pieces of ivory stained red. Two other remarkable Egyptian specimens in the national collections are tiles, one of which is rectangular and measures six by four inches; it is of the celebrated blue ware, on which is traced in a darker blue outline the figure of the royal scribe, ADMENEMAPT, worshipping OSIRIS; the other tile, which is circular, is inlaid with a very curious representation of a spider in the centre of its web.

Besides their enamelled beads the Egyptians have left, as illustrations of their social and domestic history, specimens of their draftsmen made of the same material, and various miscellaneous articles, that may have once been used either as personal ornaments, or as children's toys—the two classes of objects may often be grouped together—or for the various decorative requirements of daily life.

The same vitreous glaze which they used with such excellent effect in their enamelled silicious pottery, the Egyptians also applied with a similar aim to a vast number of works of a highly artistic character, executed by them in steaschist, or some other hard substance of the same kind. This steaschist, which closely resembles the jade employed by Chinese artists in many of their carvings, is a material that may be worked to great advantage by skilful hands. The Egyptians produced in it amulets, rings, and other objects, which are still distinguished for the sharpness and precision of their carving and their delicate finish. The stone, when cut and inlaid with niello-like incised work, was coated with enamel and subjected to the action of the furnace, the result being a species of glazed stoneware that at once bore a close resemblance to true pottery and was altogether distinct from it. Amongst the most highly finished and beautiful of the examples of these singular works of Egyptian art, that are known to be yet in existence, are signet rings and inscribed amulets. The form generally prevalent for rings executed in this manner is the scarabæus beetle, called in the language of Egypt *kleper*, or creator, and regarded by the Egyptians with peculiar reverence as the sacred emblem of the Deity, who made, as they held, all things out of clay. The hieroglyphics engraved upon these scarabæi are executed in flat intaglio, sometimes with a wonderful accuracy and delicacy, completely rivalling those on gems. On some only a solitary hieroglyphic is put; but on others as many as three lines of these symbols are inscribed. They are of all ages—from the fourth dynasty down to the Roman empire; the principal period of their manufacture was, however, the reign of TOTHMES the Third, of the eighteenth dynasty, one-tenth of these amulets bearing his name.—*Birch*. The same judicious writer directs attention to the fact, that many of these carved works attest a certain community of art in Egypt and Assyria. It is also observable that the devices, legends, and mottoes of the rings, amulets, and other objects clearly indicate that they were adapted to certain distinctive conditions of different classes of the Egyptian community.

The busy and enterprising multitudes who consti-

tuted the races that are now distinguished as ancient Egyptians, have transmitted both the salient points and the minor details of their national history and of their private life, in part written in their mystic hieroglyphics, and in part conveyed with graphic fidelity by means of the varied productions of their arts and manufactures. From both these channels of information it is evident, that a consideration of primary importance with the living Egyptian was the preparation and appropriate decoration and furnishing of his tomb. To this very circumstance posterity is mainly indebted for what is known, if not of Egypt, certainly of the Egyptians. They considered it to be right to adorn their sepulchral chambers with painted scenes and incidents, as they occurred daily on every side of them; and with the mummies of their dead they had been taught to deposit vases filled with various substances for the use of the deceased, together with a multiplicity of personal ornaments and other objects. Hence all these relics have come down preserved, as if for especial information, from century to century in their silent treasuries. The uses to which they were put by their makers have insured their preservation; and the relics themselves, in their turn, have reciprocated the good deed, by declaring in what manner the ancient Egyptians used them, and by elucidating the several purposes which they were intended to serve. Nor is the value of the ancient pottery, either preserved or represented amidst the remains of ancient Egypt, limited in its historical capacity to the land and the people of the Pharaohs and the Ptolemies. Certain fictile relics still in existence bear inscriptions which declare that they were fabricated to contain and to preserve tribute—*han*—of wine, incense, and the like, in the storehouses of the king; and there is every reason for believing that the same vessels conveyed these offerings from distant tributary lands to the banks of the Nile. The father of European history has left it on record that in his time—before CHRIST four hundred and forty years—wine was exported from Syria to Egypt in such amphoræ as are represented, tribute-laden, in the triumphal procession of TOTHMES III., and which may be seen in the national museum. Some of these very vessels, therefore, may have been sent to one of the last of the Pharaohs, who reigned in the lifetime of HERODOTUS; while others, in all probability, formed a part of the tribute paid to his more powerful predecessors. These productions of the potter may accordingly be regarded with a twofold interest, since they both call one back to the Egypt of antiquity, and also afford an insight into the condition of art amongst some Asiatic people, otherwise unknown, who were contemporary with the Pharaohs of the nineteenth dynasty.

ASSYRIAN POTTERY.—With the exception of bricks both sun-dried and kiln-burnt, and of inscribed tiles and cylinders, the ceramic productions of the ancient Assyrians and Babylonians have not been discovered in any great numbers in Mesopotamia. Nor have the bas-reliefs and cuneiform writings—so far as the latter have been read—that recent researches have brought to light in this remarkable region, done much to elucidate the practice of the potter's art as it may be presumed to have

once flourished upon the banks of the Tigris and the Euphrates. The Assyrian sculptures are art-written records, not of the Assyrian people, but of their kings: hence, any illustration of Assyrian life that these most interesting relics may afford, is rather incidental and subordinate in its character, than a primary and direct motive of the composition. Not thus did the Egyptians apply their hieroglyphics. Their Pharaohs, indeed, appear in the full and significant grandeur of their pre-eminence; but with them their people are habitually associated. Egyptian life, in every phase of its varied conditions, and in all the diversified yet ever characteristic associations of Egypt itself, was what those active and imaginative sons of the Nile delighted to depict: and hence they stand alone amongst the nations of antiquity, in their love for that graphic species of history which records and transmits to distant generations complete biographies of a people.

In addition to the innumerable sun-dried bricks that were used for constructing the enormous mounds upon which the cities of ancient Assyria were erected, a few rude figures only of unbaked clay have been found beneath the pavement-slabs of the Assyrian palaces; and these were probably placed there as propitiatory offerings. The few objects of unglazed terra-cotta which have been discovered, consist of vases and other vessels of various forms and sizes, many of them being evidently made expressly for sepulchral uses, with some lamps of peculiar shape, and some small figures and architectural ornaments. Of these the larger portion may be assigned to different periods subsequent to the fall of Nineveh, while certain specimens have been found in circumstances which prove them to have been coeval with the ancient Assyrian edifices. One saucer-shaped patera LAYARD found built into the back of a wall of the N. W. Palace at Nimrūd, evidently through the mistake of the workman. Another vessel in the shape of a cylindrical jar, eighteen inches high, and nineteen inches in diameter, was found in the same palace between two colossal bulls at the entrance of a chamber; it is of a pale yellow clay, and ornamented with Assyrian mythological figures. Other vases were discovered inside sarcophagi, also made of earthen materials. Similar objects, the greater number being sepulchral, were picked up at Kouyunjik above the ruins of the palaces in the mounds; they closely resemble the ordinary Roman pottery of the same class, and they were probably produced in Roman times, by the races who established themselves upon the huge mounds after the fall of the buried cities. Vases of the same class have also been found at Khorsabad, and examples of terra-cotta coffins have been exhumed at Kalah Shergat. The ornaments of all are of a very simple character, and there is but little to distinguish as Assyrian such of these works as are not unquestionably of a high antiquity. It has been remarked that this terra-cotta ware evidently continued to be made till a late period in the country that once had been Assyria, since vessels have been discovered there having covers inscribed with Hebrew and Syriac characters. The old Assyrians would certainly have written upon these vessels their own arrow-headed inscriptions. They may be as late as the fourth century after CHRIST. It must be added,

however, that it is by no means impossible for some few ceramic relics of the old Assyrian period to be intermixed amongst this more recent pottery. The terra-cotta figures and architectural ornaments of the Assyrians, like those of Babylonia, were probably coated with rich gilding, and consequently they may for this reason have perished through the cupidity of the spoilers. The few relics of this description that have been discovered are small in size, and by no means worthy of high admiration as works of art. Besides the figures, some moulds for making small figures have been found formed of terra-cotta—also some seals, now in the British Museum, about an inch in diameter, of which the material is fine dark clay, and which had been stamped with the device of a king stabbing a lion with a sword. LAYARD informs us that in removing one of the slabs sculptured with the hunting scenes of Ashurbanipal at Kouyunjik, several small terra-cotta figures of dogs were found, standing, made of a coarse clay covered with a blue, red, or black paste, and having names inscribed on them in cuneiform characters, such as, *the guardian of the house*, *the lion-tamer*, and others. RAWLINSON supposes these to be images of certain hounds, formerly favorites with the king, which had been killed in hunts of lions and other wild animals.

Very different from the formulæ which they impressed with stamps upon their kiln-baked bricks were the legends that, in accordance with a custom peculiar to themselves amongst the nations of antiquity, the Assyrians inscribed upon cylinders, prisms, and small tiles of very fine and sometimes highly-polished terra-cotta. Thus they wrote the records of the king's victories and the annals of his reign; thus their title-

deeds, and deeds attesting and confirming the sale of land and other properties, were written; and thus their astronomers noted down the results of their observations and calculations. A chamber filled with terra-cotta archives and miscellaneous records—books, they would now be called—was found in the palace of SENNACHERIB at Kouyunjik, one of which, a hexagonal prism of terra-cotta, inscribed with the records of a king's reign, now deposited in the British Museum, is represented in Fig. 432. Probably this chamber was the

private library of that monarch. Similar collections have been discovered in other parts of Assyria, from which there have been obtained about twenty thousand inscribed tablets, containing the native literature of the country as it issued, not from the press, but from the kiln. Thus, while the paper and parchment learning of the Byzantine and Alexandrian schools has almost disappeared after a few centuries, the granite pages of

Egypt and the clay leaves of Assyria have escaped the ravages of time and the fury of barbarism.

In addition to their terra-cotta writings, the Assyrians, in common with the Egyptians, employed the same plastic material that formed their cylinders precisely in the same manner as sealing-wax was used in Europe in the middle ages, and is still in use at the present day. The clay, when in a moist state, was either impressed upon the face of the document, or appended to it by means of a slip or cord. One of these seals, found with the terra-cottas supposed to contain the royal archives at Kouyunjik, was stamped with the signet of SABACO, who reigned in Egypt seven hundred and eleven years before CHRIST, and was contemporary with SENNACHERIB.

Glazed and Enamelled Pottery was evidently in use amongst the Assyrians for various religious, sepulchral, domestic, and architectural purposes, much in the same manner as with the Egyptians. The Assyrian productions of this class, however, are proved by such remains of them as still exist to have been inferior to those of Egypt, both in their manufacture and in their artistic qualities. Very few vases of this ware have been found in a state of good preservation amidst the wreck of the Assyrian palaces; but fragments abound in that country of ruins, which demonstrate the existence of this ware in ancient times under a considerable variety of forms, though never, as it would seem, in any great abundance. Some of the shattered fragments now in the British Museum are parts of vessels that were lined with a coarse blue glaze; others, found in different localities, are of a pale lilac hue, or they have yellow patterns on a blue ground; or the ground is white, upon which there are stripes of brown and purple: but the most prevalent color is a fine bright blue, verging towards a green when the surface has been slightly decomposed. The body of this ware is formed of the fine clay deposited during the inundations of the great rivers, the glazes being a vitreous silicated substance variously colored with metallic oxides. A recent analysis has shown, that the opaque white employed in the decoration of an Assyrian enamelled brick was produced with tin, the yellow with antimoniate of lead, the brown with iron, and the blue and green with copper; the flux and glazes proved to consist of silicate of soda and lead. The enamel—as was proved to be the case from its having trickled down the sides when in a melted state—was placed only upon one surface of the brick, with the view to securing its adhesion; and the brick itself was laid horizontally, with the enamelled face uppermost, when in the furnace. This brick was probably slightly baked before it was painted, and then when the colors had been applied to it after it had become cold, it was a second time placed in the furnace. The walls of Nimrūd were evidently faced with these enamelled bricks, that were variously colored and otherwise decorated, and thus formed an effective species of mosaic. Architectural cornices and other decorative accessories were also formed in a somewhat similar manner from different pieces of this enamelled terra-cotta.

BABYLONIAN POTTERY.—In their construction from sun-dried bricks almost identical with those that were

raised by the Assyrians higher up the streams of the great rivers, the vast ruined mounds of Babylonia yield various ceramic relics, that bear a close general resemblance to the corresponding remains which have been discovered under similar circumstances in Assyria. These examples of pottery are not sufficiently numerous to supply detailed information respecting the fictile processes of Babylonia. The pottery of these mounds, also, is composed of productions of very different periods, the works of distinct races. Some without a doubt was made in the days of Babylonian greatness; but the greater portion must be assigned to eras subsequent to the fall and ruin of the city and empire of the Chaldees, when various races succeeded each other in the occupancy of what once had been Babylon.

The cups, vases, and other vessels of terra-cotta in use by the Babylonians, appear to have been of a simple character. The paste is generally of a light red color, but sometimes of a yellow hue, with a tinge of green; and it has not been submitted to the action of a very high temperature. The figures were produced in moulds; and the vases, formed upon the wheel, were devoid both of painting and any other decoration. In the case of the larger specimens, modelled figures and heads were sometimes introduced at the handles for the purpose of adornment. A few small pieces of very fine terra-cotta have been found in this region, in the form of bas-reliefs of great interest. One, the best of the series, now in the British Museum, represents a man holding by the collar a very large and noble-looking dog. The design has been modelled by the hand, and it is remarkable for its spirit and freedom. This specimen was obtained near Babylon. Other small bas-reliefs of female figures have been found at Warka; but they have all been produced from moulds, and may be assigned to a less remote period. The larger statues, such as would be made to represent the gods and heroes of Babylon, may be considered to have been formed of terra-cotta. Such was the image made of clay and metal, recorded by DANIEL to have been seen in his dream by NEBUCHADNEZZAR; and such, too, was that other image of Bel, declared by the same prophet to have been composed of clay, and then covered with a coating of brass or bronze. The colossi mentioned by DIODORUS, were probably produced in the same manner; and the famous golden idol of NEBUCHADNEZZAR may have been a work of the king's potters, overlaid—as was the custom amongst the Babylonians—with rich and costly gilding.

Gilding, overlays of silver, and variously-colored glazes were applied by the Babylonians to the bricks with which they constructed their more important edifices. The walls of the Median Ecbatana are described by HERODOTUS as having been built with bricks of different colors; and the supposed temple of Belus at the Birs Nimrūd affords another remarkable instance of the same polychromatic construction. In 1854, Sir H. RAWLINSON dug out from the angles of the stages of the brickwork three inscribed cylinders, from which he has discovered that the Birs Nimrūd was dedicated by NEBUCHADNEZZAR to the seven planets; the building was, accordingly, constructed in seven stages or platforms, each one smaller than the one below it,

and formed of bricks differently tinted. Mr. LOFTUS has added much very valuable information to what had been previously ascertained upon the subject of Babylonian pottery. At Warka he found walls formed of sun-dried bricks, banded at intervals with layers of reeds; some of these bricks were stamped with inscriptions. Kiln-dried bricks of small size, and red brick cones similar to those constantly to be seen in Egypt, were discovered at the same place; the latter had their bases colored red, and they were embedded in a cement of mud and straw as building materials. At Warka, also, Mr. LOFTUS found an edifice built of similar cones, three and a half inches long, and laid horizontally, their crests and bases alternating, and embedded in cement. They were formed of a dull yellow clay; but, their bases having been dipped in black or red paint, they thus might be arranged in such a manner as would form various ornamental patterns. Ornamental brickwork constructed of bricks of the ordinary shape and executed with singular skill, together with enamelled bricks of various hues decorated with stars having seven rays; a pavement of vitrified slabs; glazed lamps of terra cotta; and most curious coffins of enamelled ware in the shape of gigantic slipper-baths—were amongst the fictile relics discovered by this indefatigable explorer at Warka, which appears to be identical with the ancient Ur of the Chaldees. The Warka coffins were found in prodigious quantities, piled up to the height of forty-five feet. They were formed of pale straw-colored paste, imperfectly baked; the whole being covered with a blue glaze that has acquired a greenish hue through age. These singular relics Mr. LOFTUS assigns to the Sassanian period of Babylonian history, when Warka must have been a vast necropolis; they are variously ornamented with raised bands and patterns, and also with numerous small figures in low relief, and they have richly adorned lids of the same material with themselves that cover the openings. Several specimens have been added to the oriental collections in the British Museum.

Fragments of glazed or enamelled pottery are intermixed with the debris of the common terra-cotta wares throughout the ruins of ancient Babylonia, and they consist of the remains of vases and different vessels in addition to the colored bricks so much in favor with the Babylonians.

Documents inscribed upon cylinders and slabs of fine terra-cotta after the custom prevalent amongst the Assyrians, have been discovered in the ruinous heaps that have of late attracted so much attention in the ancient Babylonia Proper. These terra-cottas exhibit great varieties in their forms, but, so far as they have been deciphered, appear to comprise precisely the same classes of records with those of Assyria. In one fragment, at the edges there are the names and seals apparently of the witnesses who attest a deed. Another fragment of the utmost value is a part of a great cylinder, now in the museum of the India House, and containing, according to Sir H. RAWLINSON, a transcript of the statistical tables of NEBUCHADNEZZAR, in which the temples either built or endowed in Babylonia by that monarch are enumerated. Several other Babylonian cylinders are preserved in the various museums of Europe. Sir H. RAWLINSON states that they are seven in number, or

rather that there are seven distinct historical records preserved on as many different cylinders. Of these records, the one that describes the Birs Nimrūd, is repeated in each of the three cylinders that he himself discovered in that celebrated heap of ruins.

ETRUSCAN POTTERY.—As in Egypt and Assyria, so also in Europe, the first appearance of the potter's art is coeval with the first dawn of civilization. In Etruria, that region of Italy which lies to the north of the Tiber, from a remote antiquity the remarkable race were established who gave their name to the country where they flourished, and whose half-legendary history is the earliest that appears in European annals. It is a custom prevalent amongst writers upon ancient art, to describe the Etruscans as having obtained from Egypt the original germ of all their art-industries; it would, however, be difficult to demonstrate the fact of any intercourse between Etruria and Egypt, antecedent to the earliest operation of Etruscan art. The fact appears to be that the Etruscans, like every other people, *in the first instance*, were the inventors of their own arts, and applied their inventions to meet the requirements of their daily lives. It is true that there is conclusive reason for considering the sombre and severe spirit of the Etruscan race to have been rather receptive than productive; and, consequently, this remarkable nation is found readily to have accepted and appropriated to its own use whatever improvements in the arts it might have discovered during the progress of time, through a gradually-extending intercourse with foreign visitors. Thus the arts of Egypt, transmitted through the Greeks, may be said ultimately to have reached Etruria; and thus the Etruscans, having been instructed in their style by the artists of Greece, conformed to the Greek system, and in fact appropriated it as their own. But, on the other hand, it is no less certain that the primitive Etruscans were possessed of sufficient inventive powers to produce an indigenous pottery suited to their own wants, and the materials for which nature had strewed in abundance at their feet.

The earliest, and as would naturally be expected, the simplest relics of Etruscan pottery that yet remain, must be attributed to an era long subsequent to the general practice of the ceramic art in Etruria—that is, they appear to have been produced in the eighth and seventh centuries before this era. They chiefly consist of vases of a dark color, fabricated from a coarse brown ware, and in some instances apparently modelled in imitation of vessels formed of wood. These vases vary considerably in size, and many examples are adorned with figures in relief; but no instances have been observed in which paint was used as a decorative medium. They have been for the most part discovered at Cervetri—the ancient Caere—Vulci, and Chiusi; and it is evident that they were not by any means first efforts in the practice of the potter's art. Indeed, seven hundred years before CHRIST, the Etruscans had been a flourishing people. It is a subject for much regret that the history of European pottery, which opens upon Etruscan ground, should not be able to trace out its course clearly from its original fountain-head; but the antiquity of Etruria, as a country regularly inhabited by a race who enjoyed at least a comparative civilization,

intercepts the researches of the historical inquirer, and convinces him that he must be content to commence his record with the earliest actual specimens of Etruscan fictile works, that time has been willing to transmit to the present age. The want of a literature amongst the Etruscans, also, adds seriously to the difficulties which attend the investigation of the ancient arts of Etruria. Roman writers, however, have supplied much information that might naturally have been expected from the Etruscans themselves. It is chiefly by this means that the knowledge possessed of the more important works of the ancient Etruscan potters is derived, since the Romans, in the early days of Rome, unable to execute such works, were obliged to have recourse to Etruscan artists for the plastic decorations of their temples. Such testimony is conclusive in establishing the fact, that the Etruscans at a very early period had established a school of art peculiarly their own, which, in its characteristic features, had attained to a high degree of perfection.

According to PLINY, the art of working in terra-cotta was principally cultivated at an early period in Italy by the Etruscans. The same writer states that the art of statuary was so old in Italy that its origin was unknown. One may reasonably infer that in the days of PLINY the origin of the potter's art in Europe was equally obscure; and thus, accordingly, it may be safely conceded to the Etruscans—the people amongst whom that art appears to have been known and practised from a remote antiquity. BIRCH suggests that the Etruscan potters may have worked from foreign models, and perhaps from the statues of the Egyptians, with which they first became acquainted when PSAMMETICUS I. threw open Egypt to the commerce of the world in the second century of Rome, six hundred and fifty-four years before CHRIST. But Etruria had attained to celebrity for its pottery before Egypt had been made accessible by Etruscans; and, in fact, there exists no really valid reason for withholding from the Etruscan potters the credit of producing their own pottery from their own designs, until the potent influence of Greek art appears to have prevailed over the native sympathies of the Etruscan people. The change thus effected may be said to have taken place during the first half of the fifth century previous to the Saviour. Prior to that period the arts of Etruria may be regarded as Etruscan, and therefore independent of Hellenic influence.

With the exception of vases, of which vast numbers have been found, but few productions of the Etruscan potters have been preserved until the present day. The safety of the vases has been the result of the free use made of them by the Etruscans themselves in their sepulchral rites. They deposited numerous vases in their tombs, and closed them up in the same security that they so studiously sought to obtain for the remains of their dead. And the fictile relics rested undisturbed for centuries, until the inquiring and exploring spirit of modern times should exhume them as monuments of ancient history. The statues and reliefs in terra-cotta for which the Etruscans were celebrated, with their architectural works executed in the same material, would almost inevitably perish in the sharp vicissitudes of succeeding years; and, indeed, such examples

as do exist owe their preservation to the circumstance of their having been deposited, like the vases, beneath the surface of the ground.

Bricks and tiles appear to have been but little used by the Etruscans, except for sepulchral purposes. The recesses of the chambers that held the small sarcophagi within which the ashes of the dead were deposited, were closed by tiles bearing inscriptions; and similar tiles, at a much later period, were used to cover such bodies as were interred, and not burnt. Various decorative accessories of the tombs of an architectural character, were also modelled in terra-cotta; and there is every reason for believing that friezes, antefixæ, and other architectural details formed of the same material, were in general use. Recent excavations in Etruria, however, have failed to produce examples of genuine architectural bas-reliefs, such as were so freely introduced into their buildings by the Romans. Terra-cotta sarcophagi have frequently been found, which are identical both in their general character and their style of adornment with the more costly works of the same class in alabaster, tufo, and other similar materials. Some few are of sufficient size to receive a human body laid at full length. The British Museum contains two such sarcophagi, which have been obtained from Vulci: their sides and ends are covered with bas-reliefs, and on the covers there repose recumbent effigies of Etruscan females, modelled at full length. The paste of which these terra-cottas are composed, is either a pale red or a pale yellow in color. But Etruscan terra-cotta sarcophagi more generally are very small, and appear at first sight to be models rather than actual depositories of the remains of the dead. They were intended to be the receptacles of the ashes after cremation, and they may be regarded as the prototypes of the sepulchral urns which the Romans ranged in rows of small cells or niches, around their *columbaria* or sepulchral chambers.

The effigies that rest upon sarcophagi are the only statues of full size in terra-cotta by Etruscan artists, which are known now to be in existence. The few examples that have been discovered closely resemble in their artistic treatment the early bronzes and sepulchral wall-paintings of Italy. It does not follow from this circumstance that the terra-cotta figures were modelled from types either in metal or from paintings; on the contrary, the resemblance between these figures, executed by different processes, simply confirms the independent and consistent action of the artists of Etruria. A most remarkable recumbent effigy in pale red terra-cotta, having the clay intermixed with volcanic sand, was found at Cervetri, where other somewhat similar figures have also been discovered, all of which are genuine Etruscan, and apparently older than the foundation of Rome. Besides the monumental figures, some few curious and interesting busts have been found, formed of clay, in the sepulchres of Etruria.

The VASES of the Etruscans admit of the following classification:—

1. Vases of brown terra-cotta.
2. Vases of black terra-cotta.

3. Vases of red terra-cotta.

4. Vases painted.

Also a small class of vases of a yellow ware.

The brown vases have already been stated to be the oldest existing specimens of Etruscan pottery. Their color is a greyish brown, and sometimes the clay is red in the centre. They are in various shapes, the most curious being an example in the British Museum in the form of a *Tugurium*, or ancient Etruscan cottage—Fig. 433—with a movable door and a vaulted roof that

Fig. 433.

apparently was intended to represent the beams of the timber-covering of an actual dwelling. The ashes of some deceased Italian, who may be considered to have lived and died before the name of Rome had been spoken amongst men, were inserted through the door, which was then secured by a cord. The smaller vessel was then placed within a large two-handled vase of equally rude character, and thus protected from the superincumbent mass of earth.

It is a remarkable fact that hut-shaped sepulchral urns have been discovered in several parts of Germany, which closely resemble those that once were buried in the tombs of Etruria. The German specimens are distinctly Teutonic; and they are to be attributed to an age before the predominance of Roman art, but while bronze weapons were in use. One found at Mount Chemnitz in Thuringen, is cylindrical with a conical roof or cover; a square orifice in this vase represents the doorway or window of the hut, through which the ashes of the dead were introduced, when the whole was secured by a small door fastened with a metal pin. Similar vases have been exhumed at Roenne, Parchim, and in the island of Bornholm. A vase of this description, found at Aschersleben, has its cover modelled in the form of a tall conical thatched roof, and it has the door with its ring still remaining. Another, with a taller body and flatter roof, with a door at the side, was discovered at Klus, near Halberstadt. The larger vases were used to contain and preserve the ashes of the dead; and they are found in some instances to have been placed, for greater security, within vases of coarser fabric and a different shape, or to have been protected by some covering of stones or tiles. The

other smaller vessels held the offerings, consisting of different viands, that the Teutonic races deposited with their dead.

The ancient brown vases of Etruria are not uncommonly found beneath beds of lava. Many of them are highly polished by friction, so that they have the appearance of basalt, but they have no glaze upon their surfaces.

Next in the order of time are the black vases, some of which are thick and heavy, while others are thin and light. The black surfaces of many of these vases have a lustrous jet-like polish, which occasionally may have been produced upon the lathe. They frequently exhibit traces of the imitation of other Etruscan works of art in both wood and metal; but they show no signs whatever of any imitation of foreign productions. In the earliest examples the ornamentation consists simply of rude zigzags, spirals, and festoons of lotus-like flowers and similar devices, hatched upon their surfaces. Somewhat later animal forms, with human figures, heads, and other objects, make their appearance. These figures are commonly disposed so as to form friezes running round the body of the vase. They are generally in a bold relief, which has been obtained either from the impress of dies, or by modelling, or by passing a cylinder cut in intaglio round the vase while the clay was moist. The treatment of the figures in these friezes is peculiar, and it not uncommonly indicates that the rudeness of the work has resulted rather from the intractable nature of the material, than from the incapacity of the artist. The early usage of producing ornaments by means of incised lines, is occasionally introduced for the purpose of carrying out the details of the reliefs. The designs of these friezes are obscure and uncertain; and, in connection with the absence of inscriptions having reference to either the subjects, the artists, or the potters, they serve to corroborate the assumed high antiquity of the vases. When inscriptions do occur, they appear to be merely the potter's memoranda, which were scratched in with a pointed instrument at the bottom of the vases after they had been finished. Vessels differing very greatly from one another in form and size, and evidently no less different in their several uses, have been found of this ware; amongst them are cinerary vases of the most singular character, being rude representations of the human figure. Collections of these vases have been found in many sepulchres, which contain various vases and other objects, the use of which is unknown. Large vases sometimes contain numerous smaller ones; spoons also and vase-stands have been found with them. It is probable that JUVENAL referred to pottery of this class, when he spoke of the *black saucer of Numa*; and that this is the black ware that PLINY records to have been fabricated by the corporations of potters in the days of NUMA, seven hundred years before CHRIST. HORACE, MARTIAL, and JUVENAL also appear to have had it in view in certain well-known passages of their writings. The tombs which have produced these vases in the greatest abundance are in the vicinity of the ancient Veii, Cære, Clusium, and also at Volaterra and Cortona; but they very rarely occur to the south of the Tiber. An analysis of the

paste of the black Etruscan vases has given a mean result of—

	Centesimally.
Silica,	63·24
Alumina,	14·42
Oxide of iron and manganese,	7·80
Carbonate of lime,	3·25
Carbonate of magnesia,	2·12
Carbon,	1·83
Water,	7·34

100·00

The vases of red ware, which may be assigned to the earliest period of existing Etruscan pottery, are found in the same ancient sepulchres with the black vases, but in much smaller numbers. These vases are of a dull red hue, and of a gritty material, apparently containing an admixture of the tufo of the soil. If large in size, their bodies are reeded, and ornamental patterns are boldly modelled about their necks; sometimes they have handles; and the characteristic Etruscan frieze appears in some of them, with representations of animals, chariots, hunting scenes, and banquets. They generally are found standing in flat circular dishes or saucers, of similar ware, but made of a finer paste, and ornamented with other friezes impressed upon them in bas-relief with a cylinder. Some few vases of this class, instead of a decided red, are of a pale salmon tint; and they have a slightly freckled appearance, which is produced by black specks of some volcanic substance mingled with the clay. The Etruscan sepulchres also continually produce vases of a pale yellow color and of a fine quality, some of which are probably of very ancient date, while others appear to have been manufactured at subsequent periods.

Some vases found at Cære, composed of a pale reddish-brown clay, specked with black volcanic sand, and sparkling with mica, are amongst the earliest specimens of the *painted* pottery of Etruria. They are adorned with various patterns, and also with flowers and figures, painted in white upon a black back-ground, or upon the clay in its natural color; the peculiarity of the work being that the painting was executed after the manner of an opaque fresco, and not burnt in upon the vases in the furnace. These painted vases may have been produced a century or more anterior to the mythic arrival of the Greek potters, who, according to PLINY, were brought by the fugitive DEMARATUS from Corinth to Etruria between the years five hundred and twenty and six hundred and sixty before CHRIST. To this incident has been attributed the first introduction of archaic Greek vase-painting amongst the Etruscans. The Etruscan sepulchres have yielded many vases having pale buff back-grounds, upon which figures of animals are painted with fantastic and floral borders, all in a deep-red, that may be assigned to this period.

Next in the order of chronological succession are the red or orange-colored vases with black figures, the subjects being generally mythological, and the execution of them indicative of at least some progress in the art of pictorial representation, though still there is much of rudeness that lingers about them in combination with a strange uncouthness in many of the figures. In other examples the adjustment of the colors is reversed, and

the figures are red upon a dark ground. These figures are relieved by lines of black, obtained by cutting down through the red pigment to the black glaze of the vase. This same arrangement of the tints prevails in the finest and most perfect specimens of Etruscan and Italo-Greek vase-painting. The figures are red upon a ground of polished black. These vases were produced after Greek art had found a second home in Italy; and, consequently, though both made in ancient times and at the present day discovered in Italy; they may be classed with the works that were produced by Greek ceramic artists. The shade of the ground in some of the Etruscan vases is a dark-brown; in others the clay is ash-colored; and in both cases the designs are painted in black and crimson, with incised lines executed with a graving-tool, to mark the outlines of the figures with more distinctness, and also to impart the effect of energetic action to the development of the muscles. The figures are very generally represented on a ground *semée* with flowers. In addition to those vases found in Etruria, which must be distinguished as Italo-Greek from their having been made by Greeks resident in Italy, many imitations of Greek vases of every kind were made by Etruscan potters throughout the period in which their own artistic powers were experiencing a continual decline. In these examples certain Greek attributes are rendered after an Etruscan manner, and the whole work is destitute of both originality and feeling. The subjects generally show traces of Etruscan influence, and often resemble the relieved friezes of the true Etruscan solid black ware. A paler ware was also manufactured at the same time, with unimportant subjects, and figures badly drawn and painted of a pallid tint, and with a glaze of a leaden hue. Other pale vases of still later date have been found in the sepulchres of Orbetello and Volaterra, with figures armed after the Roman fashion, painted of a light tone, the accessories being white, and the glaze devoid of lustre; and, in their turn, these last vases are succeeded by others, in which various figure subjects, with old Latin inscriptions, are painted in opaque white upon a black ground. Their date is about two hundred years before CHRIST.

The *inscriptions* which are associated with the subjects that appear upon Etruscan vases, like those on the Greek, are either painted in an opaque white or red upon the glaze, and are descriptive of the figures and incidents represented in the paintings, or they are incised; in the latter case the inscriptions generally refer to the proprietors of the vases. Many of these inscriptions are very difficult to read, from the rudeness of the Etruscan language in which they are written, and also in consequence of the obscurity of the legends themselves.

The same sepulchres that have supplied such abundant and diversified stores of the ceramic productions of the ancient Etruscans, have also preserved numerous examples of their exquisitely engraved gems, of their noble bronzes, and their beautiful and delicate gold filagree work. However admirable many of their vases may be, with their pottery the Etruscans never were so successful as with their works in metal. And the Etruscan artists evidently felt that they were able to

exercise a more complete mastery over metals than over clay, since it is found that in their best and most characteristic pottery they have assimilated their fictile productions to their bronzes. This assimilation ceased as soon as the ceramists of Greece had established themselves in Etruria. From that time the Etruscan potters conformed to the Greek system, and the finest ceramic works that thenceforth were produced in Etruria must be distinguished as Etrusco-Greek—they were the productions either of Greeks who had settled in Etruria, or of Etruscans who had been instructed and directed by Greeks. The grand distinction, then, between the two great classes of Etruscan sepulchral deposits is this, that the most admirable pottery is Etrusco-Greek, while the best metal-work is genuine Etruscan. Still, in the same deposits pottery is found in abundance, which is no less truly Etruscan than the works in metal, and which, at the same time, possesses many qualities that are eminently meritorious. In treating of the pottery of Greece, it will appear that the most precious relics of that wonderful art-manufacture have been discovered in far greater numbers in Italy than in Greece itself. In Etruria the Greek settlers produced in abundance a pottery that was thoroughly Greek, and their Etruscan contemporaries both imitated their productions and conformed to their style. A few lingering traces of the old native feeling and association may occasionally be discerned in vases, which appear to indicate that they were produced by Etruscans in Etrusco-Greek times, while the Greek style was in the ascendant, and yet before Etruscan usages and habits had been altogether superseded. It is remarkable that, in the prolific deposits which have been discovered wherever the cities and cemeteries of Etruria have been explored, vases have been found that were genuine Etruscan in the same group with others no less essentially Greek. At Corneto, the ancient Tarquinii, the discoveries have been rich in the most characteristic specimens of pure Etruscan vases, black and solid, with embossed figures. The same may be said of Sarteano and Perugia, and more particularly of Cervetri or Cære, and of Veii, now Isola Farnese, and of Vulci, or Ponte della Badia. At Veii and Vulci, with the embossed black ware, painted vases and others of every variety produced in Etruria have been found. The sepulchres at Vulci have also yielded immense quantities of plain solid black vases, and of others that are painted black only, which were found in immediate association with bronzes, ivories, gold filagrees, and other objects peculiarly Etruscan. And, with these evident relics of the native pottery of Etruria were discovered, in equally great numbers, vases of the Italo-Greeks in the utmost variety, and of the highest excellence. These vases were in all styles and of all epochs of art, including both those with maroon figures upon buff grounds, of the primitive archaic period, and the various productions of the latest decadence. The sepulchres themselves were most simple and unpretending; but their ceramic contents, which for the first time were systematically explored in 1829, have never been surpassed in value and interest. The finest known specimens of vases with black figures, including such as have the black figures represented upon white

grounds, have been found at Vulci. No less remarkable also for beauty of form, for excellence and energy of drawing, and for the vivid richness of their glaze and color, are the Vulcian vases with red figures. The numerous inscriptions, also, with which these vases abound, and the occurrence in them of subjects new to classical authorities, combine with their admirable artistic qualities to enhance their importance; so that these deposits may be considered to have effected more for the advancement of our knowledge, not merely of ancient pottery, but of ancient art also, than any previous discoveries. Very remarkable discoveries of Greek pottery have been made in many other parts of Etruria, but none that may be put into comparison with those that disclosed the long-hidden treasures of Vulci. Many of the finest and most characteristic specimens from almost every principal discovery in Etruria, have been added to the ceramic collections of the British Museum.

GREEK POTTERY.—Under this collective term it will be understood that the productions of Greek ceramic artists are alike comprehended, whether their works have been preserved and discovered within the limits of Greece, or either to the West or East of Greece Proper, in Italy and Asia Minor. Whatever the region that may have produced it, as the result of modern investigations, in all true Greek pottery the impress of the arts of Greece is equally apparent; and all the relics of those arts may, accordingly, with the most strict correctness, be grouped together.

The Greeks resembled other nations in their having established a pottery manufacture of their own for their own use, at the earliest dawn of their history, and, indeed, before their history had succeeded to the era of mythic legends. The earliest productions of the Greek potters also, like those of other countries, comprised works in the three varieties of sun-dried clay, kiln-baked terra-cotta, and a similar terra-cotta covered with a glaze, which last class of fictile productions has commonly, but erroneously, been designated porcelain. In addition to building materials, the ancient Greeks formed various objects in sun-dried clay, which they applied to the internal decoration of their temples and dwellings; and PAUSANIAS has recorded the existence in his time of a statue of PROMETHEUS in this material. As a matter of course, these fragile productions have long ceased to exist, and have left the practical elucidation of the pottery of the Greeks to those other works which, instead of representing the lineaments of PROMETHEUS himself, have acquired both strength and durability through the action of the Promethean element, fire.

The use of simple unglazed terra-cotta amongst the ancient Greeks was very extensive. It provided for the requirements of daily life, and it was equally ready to supply what might be demanded for more important purposes, whether in religious and votive matters, or in connection with incidents of public interest, or for every species of decoration. Terra-cotta, also, was in constant request with the Greeks in connection with their sepulchral and commemorative usages. Friezes and other architectural members of the Greek temples were, in some instances, executed in terra-cotta; but

the examples that remain in Greece are of a period after the establishment of the Roman dominion, and those of Southern Italy and Grecia Magna can scarcely be considered purely Greek. Statues, statuettes, and miscellaneous figures, with bas-reliefs, and other objects in more salient relief, were produced in the same material in great numbers. Terra-cotta was also employed by the sculptors and other artists of Greece for modelling their compositions, before they proceeded to execute them in more costly materials. Objects of various kinds in terra-cotta once existed in immense numbers at Athens, as may be inferred from a passage of Demosthenes. It appears that there were competitive exhibitions of these plastic works at Athens and the other cities of Greece on certain festive occasions, a circumstance that will account for the artistic excellence to which they commonly attained. Such works continued to be produced until a late period of the Roman empire; and yet, but few examples of fine Greek terra-cottas have been handed down. They were but sparingly used in the tombs, and, therefore, they have perished amidst the wreck of shrines and palaces; and with the homes of the Greeks who made and fashioned them, they have disappeared from the face of the earth. Neither have the terra-cotta moulds, that were certainly used for the casting of bronze statues, been discovered. Small figures, however, made by the same process by inferior artists, which once were used by the Greeks as ornaments or as household gods, and which closely resemble modern plaster casts, have been found in abundance near the sites of many of the cities of antiquity. The paste employed in producing their terra-cotta figures by the Greeks, is distinguished from that of the vases by its being softer and more porous. It yields easily to the touch of a steel instrument, and emits a dull sound when struck; nor does it attain to any great degree of hardness when submitted to a high temperature. Its color varies from a deep-red to pale-straw; and a similar degree of variety may be observed in the texture and density of objects from different localities. The terra-cotta of antiquity may be distinguished from modern works of the same class, by its greater lightness as well as by its softness.

The terra-cotta figures and architectural ornaments of the Greeks, were constantly painted by a body of artists who appear to have devoted themselves entirely to such occupations. They adopted both a conventional system of polychromatic adornment, and also such coloring as might be considered to have been based upon the natural and appropriated distribution and harmony of the different tints. Gilding was occasionally introduced, though, as it would seem, only with a sparing hand. The colors employed were apparently in most cases derived from coarse earths, of the same kind as those from which the ware itself was fabricated. Colors of metallic origin were more rarely introduced. Egypt supplied smalt for the cerulean blue; a Cyprian blue was also used, and subsequently indigo. Other colors were obtained from various parts of Greece, or from Greek colonies and dependencies. PLINY, as quoted by BIRCH, speaks of a painter upon terra-cotta in the words, *figlinum opus encausto pinxit*; but it has

not yet been ascertained whether any examples of encaustic painting upon Greek terra-cotta have been discovered.

Amongst the almost innumerable variety of objects that the ancient Greeks made in terra-cotta, were small cones or pyramids, about three and a half inches high, and perforated near the top. They were commonly inscribed, and they are supposed to have been attached to the necks of cattle. They are frequently found in the fields in Attica and other parts of Greece. Similar cones have also been found, which are perforated vertically. Some specimens, almost of a bell-shape, were discovered near Sebastopol and at Kertch. Small flat discs of pale-red or yellow terra-cotta, pierced with two holes, and ornamented on one side with a star in relief, and with the letters A and E on the other side, have been found in excavations at Tarsus. Others have been discovered in Lycia.

The Greeks habitually made from baked clay the lamps which provided light within their dwellings. They are found to have assumed a great variety of shapes, many of them exactly resembling those discovered at Rome, and others differing most essentially both from the prevailing Roman types and from one another. The distinguishing characteristics of the Greek lamps, are the superior fineness of their paste, and its paler hue after leaving the furnace, their smaller size and more delicate art, and, above all, their inscriptions. The Greek lamps of terra-cotta that have hitherto been discovered are all of the period of the Roman dominion, and consequently they may be grouped with corresponding works produced in other parts of the empire. In the neighborhood of ancient Greek cities they exist in great numbers. Several hundreds have been taken from excavations at Tarsus and at Calymna, and many other places have been almost as prolific in these interesting fictile relics of the Greeks.

GREEK VASES.—Fictile vessels of various shapes and sizes were employed by the Greeks, as they were by the Egyptians, for every conceivable purpose which it would be possible for them to accomplish. They performed the several duties which are, in this country, assigned to casks, boxes, cases of whatsoever kind, baskets, and such articles of furniture as are intended to contain and preserve different articles, as well as those offices which are considered to be peculiarly appropriate to pottery and porcelain. The vases of the Greeks accordingly admit of a ready classification, not only in their artistic capacity and their chronology, but also in reference to the uses which they were severally intended to fulfil. By far the greater number of these vases was decorated with painted figures and various devices, and their surfaces were covered with a glaze; but there were some varieties of vases which, in addition to the glazed examples of the same classes, were made in great quantities in simple unglazed terra-cotta. The most capacious of these terra-cotta vases, were tubs or casks called *pithoi*, and they were calculated to contain enormous quantities of wine, honey, corn, or other stores. They have the shape of either oblong or globular caldrons, with wide mouths. When full the *pithos* had its mouth closed with a large circular stone entitled *kithon*. Fragments only of *pithoi* have

hitherto been found in Greece itself; but Italy has yielded some complete specimens of gigantic dimensions. Others have been discovered in Asia Minor, and still more recently in the Crimea. They were constructed by a peculiar process, which may be described as plastering the clay upon a frame-work of wood. The *pithoi* are best known from the circumstance of Diogenes having established himself in one of them, as in a domicile well suited to the simple requirements of a philosopher, from which he stretched out his body on

the occasion of his celebrated interview with Alexander. This incident is represented in some works of ancient ceramic art—Fig. 434—one of them, a fragment of a lamp, being in the British Museum.

The terra-cotta vase that was in most general use, both for commercial and domestic purposes, was the *amphora*. It is either cylindrical in form or egg-shaped, and always has two handles. The cylindrical amphora—Fig. 435—has a tall neck, on either side of which the handles rise from the shoulders to the head of the vase. Its base is generally a solid cone, for the purpose of fixing it in an upright position upon the deeply sanded floor of the storehouse in which it would be deposited. Amphoræ of the form represented in Fig. 436, are much less common than those of the cylindrical figure. These vessels of the long shape are represented upon Athenian and other Greek coins. Upon the silver tetradrachmæ of Athens, they appear lying horizontally with an owl perched upon them, and they probably allude to the Attic export trade in oil, which was shipped in these vases. Throughout Greece itself, and

Fig. 434.

Fig. 435.

Fig. 436.

Fig. 437.

wherever Greek influence had ever extended, there the remains of amphoræ have been discovered. In many

instances the vessels themselves have been preserved ; but the more prevalent relics are the handles, which are constantly found in great abundance when all other parts of the vessels have disappeared. These handles are either slightly curved, as in Fig. 435, or they rise perpendicularly from the body of the vase, and are attached to its head by horizontal shoulders, after the manner of Fig. 437. The handles are solid, and vary in height from about ten to twelve inches, the amphoræ varying from three to four feet. A peculiar interest attaches itself to these amphora handles, in consequence of their being generally impressed with a stamped inscription contained within a circular medallion, or an oblong, oval, or lozenge-shaped cartouche. These inscriptions record the names of local magistrates and merchants, with that of some month ; and they sometimes are accompanied with a device typical of the place of their manufacture. Thus the Rhodian amphoræ are stamped with a head of Apollo surrounded with rays, or with a full-blown rose, which was the emblem of Rhodes so long as the island retained its independence, the Apollo Helios—the sun—being identical with the famous colossus. In many examples the medallion is found to have been stamped upon the body of the vase. The paste from which the amphoræ of Rhodes were formed, is singularly pure and tenacious. The color is pale externally, deepening within to a bright salmon hue. The clay of the Cnidian amphoræ is coarser than that of the Rhodian. In color it is darker and duller, and it breaks with a rugged instead of a sharp and clean fracture, displaying particles of a black micaceous sand. The composition of these vases exhibits other varieties in specimens fabricated in different localities, and the types apparent in the stamps comprehend various devices.

Greek vases in terra-cotta have been occasionally discovered, which were evidently designed for a diversity of uses. There is a vase of a pale clay in the British Museum that is covered with a coating of lime, and when found contained human bones ; this is evidently a sepulchral vase. Several other vases, also

Fig. 438.

apparently sepulchral, have been discovered in Italy. Others again, from their forms and the style of their decorations, may be presumed to have been made for ornamental purposes. The most remarkable are those that have been modelled in the forms of the heads of BACCHANTES and other figures. This last class of

terra-cotta vases comprehends many curious specimens of the *rhyton*, a drinking goblet, modelled in the shape of animals' heads, Fig. 438, or having long reeded bodies, with *œnochoæ* or jugs and other vessels ornamented with figures in high relief. Many of these objects have evidently been adapted, from works in metal, to the plastic materials that have survived the destruction of their metallic models. The tombs of Italy, and sometimes those of Greece, have been found to contain vases of simple terra-cotta, that had been substituted for the glazed ware more generally employed in the sepulchral rites then prevalent in those countries. Such vessels exhibit a great diversity, both in their sizes and forms and in their decorations. Color was freely introduced as a means for executing the decorations of terra-cotta vases of every class ; modelling in relief, however, must be regarded as the system of ornamentation more generally prevalent.

GREEK GLAZED VASES in their general characteristics resemble those fabricated in unglazed terra-cotta, their own distinctive qualities consisting in their peculiar excellence as works of ceramic art, together with the glaze that is suffused over their surfaces. The paste or body of which these vases are composed is remarkably fine and light, tender in its texture and very porous, deeper in tone than the ordinary terra-cotta, and giving forth a metallic sound when struck. In different vases, however, which possess in the same degree all the other characteristic qualities of their class, the texture varies considerably, being sometimes so hard as scarcely to admit of being cut with a knife, while in other cases it is sufficiently soft to receive impressions from a finger-nail. Natural clays, selected from their fitness for the purposes required to be fulfilled by them, appear to have been almost exclusively used by the Greek potters ; and, indeed, it is doubtful whether they ever introduced any foreign substances into their clays. As a matter of course they may have mixed together clays which, as their experience had taught them, were distinguished by contrary qualities, both before they were placed in the furnace and while exposed to the action of the fire ; and thus pastes may have been obtained which were either more or less *fat* or *dry*, and might prove more readily fusible, or might be more refractory in resisting the influence of a high temperature. For the vases of the red ware it has been supposed that the paste received an admixture of oxide of iron ; and certainly, in some of these specimens, the paste has been found to contain this metallic oxide somewhat largely. At the same time, it is most true that many clays are naturally impregnated with that substance. In the Greek vases of Campania the pastes have been proved to contain a considerable proportion of the oxide of iron, as is apparent from the following mean of eight analyses of this pottery, made by M. SALVETAT at Sévres :—

	Centesimally.
Silica,	55.88
Alumina,	18.88
Oxide of iron,	15.8
Lime,	7.48
Magnesia,	1.63
Loss,	0.33
	100.00

BRONGNIART gives the following as the mean result of his analyses of the paste of Italo-Greek vases:—

Silica,	55.49
Alumina,	19.21
Oxide of iron,	16.55
Carbonate of lime,	7.48
Magnesia,	1.76

The comparative results of several other analyses of this paste, show the wide range of the proportions assumed by the component elements in vases from different localities. In these analyses the silica varies from 55 to 32; the alumina from 24 to 15; the lime from 10 to 7; and the oxide of iron from 24 to 12.

The ordinary paste of Greek vases in other localities has a natural character, and is comparatively free from the presence of the metallic oxide.

In the paler pastes the proportion of the lime is increased. The ware has been found to fuse at 40° Wedgwood, and it certainly was exposed by the Greeks only to a low temperature. It is remarkably porous, allowing water to exude. Its extreme lightness was considered by the ancients one of its most important qualities. Certain sites in ancient times enjoyed a high reputation for their plastic clays. The excellent materials for their pottery, however, were found by the Greeks to have been distributed by nature through every region in which their artists practised their vocation.

The colors used by the artists who painted the glazed vases of the Greeks, were chiefly black, white, brown, yellow, and red; the last three being variously modified in their tone. These hues were protected, at the same time that their brilliancy was enhanced, by a fine thin glaze, which is both lustrous and transparent. The white and other hues used upon these vases are not enamels, but opaque clays, or *engobes*, painted, after sketches of the designs had been executed, upon the clay. In many specimens, from which the coloring has peeled off, the sketches exhibit an admirable freedom of hand, and the most spirited treatment. The glaze was spread over the entire external surface of the vases, except the under part of their bases, and then the vases were baked; and afterwards the painting was completed. The additional colors that were laid on after the firing, were also subjected to the action of the furnace, but at a comparatively low temperature. The white paint has been considered to have been a white alumina or pipe-clay, or a carbonate of lime; or a mixture of carbonate of lime and oxide of iron. The same oxide has been detected in the rich crimson of the oldest vases, and iron in another proportion in the lighter red. The yellow is an ochre. BRONGNIART, contrary to an opinion accepted by many persons, denies the presence of manganese in the black paint used by the Greek vase-painters, and attributes that important color to a metallic oxide. Various other theories exist with reference to the true nature of this black, which assumes different hues under different conditions. On the vases of Vulci, for example, it has a greenish hue. It often approaches a deep grey on the Campanian vases, while on those of Nola and Cære its blackness is rich and glossy, like that of polished jet.

The Greek glaze differs essentially from the lead and

tin enamels of Assyria, and the copper enamel of Egypt, since it is an alkaline silicate, containing a certain portion of oxide of iron. The black glaze employed in the Greek vases, especially those found in Campania, has been supposed to be, in great part, due to volcanic ashes spread by the brush over the parts required, the vase being then exposed to the heat necessary for their fusion. The analysis of this Campanian glaze, according to SALVETAT, produces the following results:—

Silica,	46.30
Alumina,	11.90
Lime,	5.70
Soda,	17.10
Oxide of iron,	16.10
Loss,	2.90
	100.00

Except in the quantity of soda, this compound differs but little from some volcanic ashes. In other analyses of the black glaze, the results have given—

Silica,	63.00	or	55.49	and	55.88
Alumina,	20.00	"	19.21	"	18.88
Oxide of iron,	4.00	"	16.55	"	15.80
Carbonate of lime,	9.00	"	7.48	"	7.48
Magnesia,	2.00	"	1.27	"	1.63
Water,	2.00	"	—	"	—
Loss,	—	"	—	"	73
	100.00		100.00		100.00

In executing the subjects painted upon vases, the early practice, as exemplified in vases about seven hundred years before Christ, was to sketch the figures and patterns in red upon a reddish body, and then to color the composition with a black glaze, after which the vases were fired. Engobes of white and red were added in parts, and portions of the figures were picked out by incising through the glaze with a pointed instrument. Somewhat later the design was sketched in black instead of red. In other early examples the ground of the vases is of an ash-color, and the designs were executed in black, white, and red, with incised lines. In these vases the grounds were very commonly represented as being *semée* with flowers. To this class of vases there succeed those with black figures laid upon light grounds. They have the inner lines of the figures cut down to the ground of the vases with the graving-tool, and their accessories have been picked out in crimson or maroon color, and white. About four hundred years before Christ the vases attained to their highest degree of artistic perfection, when the figures and other objects appeared in red upon grounds covered with the black glaze, which had followed the contours of the several objects. In these vases, in place of the earlier incised lines, the inner lines were executed in black with the brush—a technical change which greatly facilitated the free and effective action of the artist. The subjects represented upon the vases of this period are such as may have been suggested by the contemporary works of the great painters, and by those also of the favorite authors of the day. They for the most part represent mythic scenes, genuine historical subjects unfortunately being rare. The sepulchral *lecythi* of the same period, and the *alabastra* or unguent vessels, were formed of a fine white clay covered with a white pigment, on which designs have been traced in black,

red, and brown. The progressive decline of Greek art after the time of ALEXANDER the Great, is very clearly indicated by examples of vases still in existence, and which are to be referred to that period of decadence. In their shapes the vases gradually became less and less elegant. The subjects introduced upon them lost their noble simplicity, and became confused and exaggerated. Modelling in relief was intermixed with the painted compositions. The figures that still were painted became indistinct in their outlines, and were often crowded with details carelessly designed, and accompanied with the most unsatisfactory efforts to accomplish perspective and the effect of distance. The designs in these later vases, whatever they may be, were drawn in red upon a black ground, the inner markings of the figures having been less carefully indicated than was invariably the case in earlier examples. Patches also of white and red have been introduced into the accessories, which effectually destroy the monochrome simplicity of the earlier paintings.

The true glory of the vases of the Greeks consists in the gracefulness and beauty of their shapes. It is in their application of form in art that the Greeks may justly claim to have excelled all other nations. Whatever the particular aim of the Greek potter, the plastic material under his command assumed a chaste simplicity or a dignified nobleness of form. Greek vases, accordingly, are to be studied not merely in consequence of their archaeological and artistic interest, but also as examples of the most masterly treatment of the ceramic art. In many instances, peculiarly adapted to the requirements of Greeks who lived in ancient Greece, these vases may have ceased to fulfil the requirements of an existing generation. While, therefore, the modern potter judiciously declines to produce mere servile imitations of even the noblest Grecian models, he finds in the humblest as well as the most important vases of the Greeks, subjects for careful and thoughtful study; and he learns from them by what means he may improve the practical application of his own art, without sacrificing its originality or perverting its usefulness. And when they proceeded to apply painting to their beautifully formed vases, the Greeks did more than increase their commercial value, and improve their appearance as objects of daily use. The vases thus were empowered to transmit to distant ages the traditions of the Greek schools of art; and they became an inexhaustible source for illustrating the mythology, the manners, customs, and literature of Greece.

At first sight it might be supposed that all the Greek vases hitherto discovered, however great their variety, and however large their numbers, were either directly or indirectly designed for the express purpose of taking a part in the sepulchral and monumental ceremonials

of the Greeks. Such an opinion might have been deduced from the circumstance that every known example has been obtained from some Greek sepulchre. But upon more mature reflection, in the great majority of instances these vases appear to have been used in many ways by the living, before they were consigned to the still more secure guardianship of the dead. It has been proved that vases that had been won as prizes in the public games, were afterwards placed in the victors' tombs. In scenes painted upon other vases obtained from sepulchral deposits, various kinds of vases are represented in use; and the very forms and adornments of many varieties can scarcely fail to be accepted as conclusively demonstrative of the purposes to which they had been applied, previous to their final consignment to the sepulchres.

At a very early period of Greek history, fictile vases were not employed to receive and preserve the ashes of the dead. The Etruscans, as is proved by their cemeteries, buried their dead; the bodies being laid upon couches in the sepulchral chambers, with their personal ornaments, their arms, furniture, and vases. After the heroic age, when cremation was generally prevalent amongst the Greeks, vases began to be used as receptacles of the ashes; but they also continued to be placed in the sepulchres for votive purposes, and as either memorials of the past or in imaginary association with the future. Amongst the Romans the custom prevailed of employing fictile vases in their religious rites, including such as were connected with the inter-

Fig. 439.

ment of the ashes or remains of their dead. For such purposes the finest vases of the Greeks were conveyed to Rome, where, after the libations had been duly performed, the vases themselves were broken, and the fragments—like the broken sword-blades in the Celtic barrows—deposited in the corners of the sepulchres.

The character of the sepulchres in which the vases have been found varies considerably in different localities of Greece, Italy, and Asia Minor. Thus, the places of interment in Greece itself are graves small in size, and sunk to the depth of several feet below the surface; while in Italy, sepulchral chambers and stone-built

tombs predominate. The chambers from which the largest and finest vases have been obtained, are excavations in the rocks, such as the Etruscan tomb at Veii, represented in Fig. 439. Others of the early tombs of Italy were tunnelled in the earth. In Southern Italy, and particularly in Campania, they are large chambers beneath the surface; or smaller tombs, formed of slabs of stone, somewhat after the manner of mediæval stone-coffins, contained both the remains of the dead, and the vases that were deposited with them. Fig. 440 represents a tomb of this description, which

Fig. 440.

has been partially uncovered. In both examples the ordinary arrangement of the vases is clearly shown. The later resting-places of the Roman soldiery and of the poorer classes of Roman citizens, made of tiles, were of the same shape. Other tombs of larger dimensions are also found, sometimes carefully constructed of hewn stones, while others are formed of rough and massive stonework. The human remains and the vases are very commonly accompanied with weapons, ornaments, and other relics, of bronze, iron, and the precious metals. It is by no means uncommon to discover a large number of vases in a single tomb; thus Sir WILLIAM HAMILTON has recorded having seen a sepulchre in the archiepiscopal garden at Polignano, in which the archbishop had himself found more than sixty vases, including several of the largest size and the utmost beauty. When discovered, the vases are found to be arranged about the human remains, piled up in corners, and hung around the inside of the tomb upon hooks, or nails, of bronze or iron. Very many have received some degree of injury; others are in a complete state of preservation. Some few still retain the rivets with which, having been broken, they had been mended in ancient times. The oldest express mention of these vases in Greek authors is made by the poet PINDAR, who flourished five hundred and twenty-five years before CHRIST. Those deposited in the Athenian graves are distinctly alluded to by ARISTOPHANES. Painted vases are mentioned

by ATHENÆUS, SUETONIUS, STRABO, and the later scholiast of THEOCRITUS. To determine the age of the oldest existing specimens with anything approaching to exact accuracy, is not possible. Some seem to be coeval with the first dawn of Hellenic civilization, and many have been made at the same period with the earliest fictile works of the Etruscans. Between Olympiads eighty-four and ninety—before CHRIST four hundred and forty-four and four hundred and four—glazed vases of great excellence were produced. During the succeeding half century, the art attained its highest perfection. The close of another fifty years brought with it unquestionable evidences of an incipient decadence. ALEXANDER the Great introduced into Greece vases made of the precious metals, after which the finest varieties of fictile vases fell into disuse. Before the middle of the third century before CHRIST, PLUTARCH has represented metal vases to have been in common use at Sparta; and, consequently, it may be inferred that pottery of every kind was becoming comparatively rare. During the first century before CHRIST, vases of earthenware were entirely superseded by works in metal; and in the time of AUGUSTUS they were regarded both as rarities and as objects of antiquarian curiosity. The best and most accurate chronological classification of Greek vases appears to be as follows:—

Period I.—Archaic Greek vases, four hundred and fifty years before CHRIST.

Period II.—Fine Greek vases, from four hundred and fifty to four hundred years before CHRIST.

Period III.—Finest Greek vases, from four hundred to three hundred and seventy-five years before CHRIST.

Period IV.—Greek vases of the decadence, from three hundred and seventy-five to two hundred and twenty-five years before CHRIST.

Period V.—Debased Greek vases, after two hundred and twenty years before CHRIST.

A second classification, which has reference to the uses of the vases and their nomenclature, must be determined by their sizes and shapes, and in some degree also by their artistic character. Amongst the most important, and also the most characteristic of the varieties which may be considered to have been satisfactorily identified, the *amphora* is the best known. In their general character, the painted and glazed amphoræ resemble those in terra-cotta—Fig. 435—but at the same time they admit several important modifications of the prevalent type. The painted amphoræ generally were provided with flat circular feet, as in the example represented in Fig. 436. The forms and arrangement of these feet vary in different specimens; and other variations of design and treatment are apparent in the forms and decorations of the handles, and in the contour and proportions of the vases themselves. The style and execution of their decorative accessories necessarily depend upon the period to which they may be assigned. The amphoræ include in their numbers the most admired and the most admirable of the vases of the Greeks.

The *pithos* is a jar, with a wide open mouth, of large size.

The *stamnos*, a jar used to contain wine and oil, has two small handles, and still retains its name in Greece.

Amongst other uses, the *hyrche*, a large species of amphora, served to hold the tickets on occasions when lots were drawn at Athens. The *lagynos* is smaller, and has a long narrow neck. It was used at table by the Greeks, and is the vessel which the stork is represented in the fable to have set before the fox at dinner. The title *ascos* is applicable to several vases, which are more or less direct imitations of the *ascoi*, or wine-skins, commonly used in Greece.

The *cadus* appears to be a globular vessel for containing fluids.

Fig. 441.

Fig. 442.

The *calpis*—Fig. 441—a water-vase, used also for unguents, and sometimes made to contain the lots of the judges, is principally found in the sepulchres of Southern Italy. It has three handles, like the *hydria*

Fig. 443.

Fig. 444.

—Fig. 442—which predominates at Vulci and other more Northern districts. The *hydria* is the older type, and it has been identified from the circumstance of the word HYΔΡΙΑ being inscribed over a vase of this shape in a vase-painting, representing *POLYXENA* going out from Troy to draw water from the fountain. In other painted scenes, *hydriæ* are represented on the heads of females who have been drawing water. These vases are generally black, and are ornamented with a frieze above the principal painting.

The *crossos*, a two-handled vase, was used in water-drawing.

The distinctive peculiarity of the *rhyton*—Fig. 438—consists in its form being such, that it could not be set down except when empty. It was made in the highest perfection in the time of *PTOLEMY PHILADELPHUS*, about three hundred years before *CHRIST*.

The *lecythus*—Fig. 443—or oil-cruet, found chiefly

VOL. II.

in Greece and in Southern Italy, commences with the early vases having black figures, and terminates with the

Fig. 445.

best vases with red figures and white grounds. Another well-known vase, of a jug-like shape, and having a spout and a single handle, is the *œnochoë*, which appears in the frieze of the Parthenon; the *olpe* is supposed to be a variety of this vase. Other varieties of it are the *prochoos*, the *aryballos*—Fig. 444—the *arystichos*, the *aryter*, and the *cotylos*. The *aryballos* is represented by Fig. 444, and the *cyathos* by Fig. 445.

The *crater*, a large open bowl with two handles, used as a wine-cooler, and found in Southern Italy, has various modifications, severally distinguished as the *holmos*, *oxybaphon*, *psycyter*, and *celebe*. A stand, having a hollow reeded foot, upon which the crater was commonly placed, was called the *hypocraterion*. Various other vases of bowl-like forms, and adapted to a diversity of uses, are severally distinguished as the *clytra*, the *thermanter*, the *holcion*, and others.

Many vases, in addition to the *rhyton*, were made expressly to serve as drinking cups or *scyphi*. Of these *HOMER* mentions several varieties of unknown forms. The most celebrated vase of this class is the Tazza-shaped *cylix*—Fig. 446—which takes rank amongst the most beautifully formed of the Greek fictile works. The *cantharos* and the *carchesion*, also, were popular drinking vases, and the *phiale*, a flat and saucer-shaped vase, was almost exclusively used in religious ceremonials. In addition to those already specified, a numerous series of other names for their different vases has been transmitted to modern times in the literature of the Greeks.

The potters of Greece, like their predecessors in Egypt, used the wheel, which is mentioned in *HOMER*. The processes of modelling and moulding were also in constant use by them. To one or other of these two processes the Greek potter would have recourse at every period of his art, in order to enable him to produce the handles and certain other parts of his vases, together with such of their constructive and decorative accessories as he might desire to execute in relief. The invention of moulding, when once introduced, appears to have become generally prevalent, and to have been employed for the production of many of the smaller plastic works, in addition to the details and accessories of vases. When completed on the wheel, and after the modelled or moulded additions had been

5 E

incorporated with the bodies of the vases, the ware was partially dried, either in the sun or in a furnace, at a low temperature, and then the painting took place. When the glaze had been laid on as well as the paint, the vases were placed in the furnace and carefully

baked. The furnaces themselves are often represented in gems, and upon the vases which they produced. They appear to have been of a very simple character, closely resembling the tall ovens of the Egyptians—Fig. 430.

Fig. 446.

Amongst the Greeks themselves the vases of Athens were those which enjoyed the highest reputation. They have been found in great numbers in Athenian sepulchres, and many of the existing specimens are unquestionably

works of the very highest excellence. Some of the most admirably executed of the Athenian vases—Fig. 447—are without any decorative figures or patterns, but are simply painted black, and they rely for their

Fig. 447.

effect upon their beauty of form and the careful delicacy of their finish. Other examples exhibit a diversity of enrichments produced by the painter's art. Of these the Athenian lecythus, with a representation of ELECTRA and her attendants meeting ORESTES at the tomb of AGAMEMNON, is a characteristic specimen—Fig. 448.

The figures which are represented upon this vase will not fail to excite attention.

The neighboring isles both imported their vases from Athens, and produced other ceramic works of the same class themselves. In the other parts of the mainland of Greece vases are frequently found. Next to

Athens, Corinth has been the most productive; but, notwithstanding the ancient celebrity of the vases

Fig. 448.

made in many of the Greek cities, a small number only of relics have been discovered on their sites. At Athens there were two pottery-quarters of the city, or *ceramici*—one within, and the other without the walls. Of the isles of Greece, Samos from the oldest times was the most renowned for its fictile wares. Samian pottery was always distinguished for its hardness, and for the fineness and the brilliancy of the red color of its paste. It maintained its reputation until the days of the Roman empire, when the island supplied services of its pottery to the imperial city. Melos and Ægina were also famous for the productions of their kilns. Passing eastward, the inquirer discovers remains of ancient pottery which convince him that, throughout the Greek settlements of the Lesser Asia,

the ceramic art had flourished from the days of the earliest civilization. Such inferences are in exact accordance with the historical records preserved in the writings of antiquity. Thus PLINY has specified the qualities of extreme thinness and lightness as being characteristic of the vases of Erythræ in Ionia; and he adds that two amphoræ, peculiarly remarkable for those much esteemed qualities, the rival productions of a distinguished Erythræan potter and one of his pupils, were consecrated in a temple of that city; and the same writer has specially recorded the celebrity enjoyed in his times by the potteries of Tralles and Pergamos. These statements are corroborated by other ancient authors.

Whatever success may have attended the operations of the Greek potters in the various provinces of the Lesser Asia, they sink into insignificance when brought into comparison with the remains of Greek ceramic works that have been brought to light in Italy. On Italian soil, in ancient times, the ceramic art found a congenial home; and the Greeks who settled there worked in happy harmony with the Etruscan occupants of the country. The finest vases of pure Greek design and workmanship, and by far the greatest number of Greek vases of every class, have been discovered in Italy. Throughout Etruria, vases that are decidedly Greek in their characteristics of style and treatment, are continually discovered in close association with others in which Etruscan types are prevalent. It is highly probable that not a few of the Italo-Greek vases were imported into Italy from the potteries either of Athens or of some of the Greek isles; but at the same time it may be considered to be beyond all question certain that vast quantities of this beautiful ware were produced in Italy itself, by the Greeks who had settled

and become established there. The same general system of coloring is observed to have prevailed in all the vases of Italy, whether they are to be considered of Greek or of Etruscan origin: thus, the figures in the early Greco-Italian vases are black; but during the best period of Greek art, from the epoch of PHEIDIAS and POLYGNOTUS, before CHRIST four hundred and sixty, to before CHRIST four hundred, the figures are red upon a black ground. A curious and also an eminently characteristic example of the vases of the best Greek period is the *hydria* in the British Museum, Fig. 449, upon which is represented the device adopted by

Fig. 449.

MEDEA to induce the daughters of PELEUS to put to death their aged father. The ram, which had been restored to youth by the enchantress, is in the act of leaping from the *olla* or cauldron; he faces MEDEA. JASON is on the opposite side, and the other figures of the composition are behind these two principal actors in the scene. The design is painted in red on a black ground; the outlines are drawn in black, and the minor workings are faintly traced in red, with accessories in white and crimson. Another fine *hydria* of the same style and period, in which horses and bigæ are introduced with figures, is represented in Fig. 450. It was found at Vulci, and is preserved in the Museum of Practical Geology. In height it measures twenty-two inches.

In every district of Central and Southern Italy the active influence of Greek art is indicated by the presence of fictile remains, frequently of great excellence and in large numbers. The character of the vases, however, differs very considerably in different localities, and with rare exceptions they indicate some degree of artistic decadence. Here, as farther north, the productions of Greek settlers or works imported from Greece may be considered to be intermixed with relics in which local influences are more distinctly evident. The vases also, in almost every instance, are to be assigned to some period not earlier than the fourth

century before our era, many of them being about two centuries later. It is remarkable that after the arms of Rome had conquered Southern Italy, about the second century before CHRIST, the Græco-Italian settlements relapsed into utter barbarism. A progressive

decadence in art may be observed in the vases, as they approach more nearly to that era. Their forms are less graceful, the subjects show a painful deterioration in moral feeling, and the execution of the whole is comparatively coarse and degenerate. The Capuan vases

FIG. 450.

are among the most interesting relics that Campania has yielded to modern research. Those found at Nola are equally remarkable, and they comprise examples of all the principal classes, with a few local types. Their distinguishing characteristics are their smaller size, their peculiar elegance of form, and the exquisite beauty of their glaze, which is frequently an intense black. The figure subjects that adorn these vases comprehend many well-known mythic scenes and personages, together with incidents from private life or local history, which it is difficult, if not impossible, to explain. In the execution of these subjects, the figures are generally left in red, by painting with a rich and lustrous black glaze upon a red body or ground. The details of the figures are also sketched in with the same black glaze, and a little white is occasionally introduced. Figs. 451 and 452 show the forms and painted decorations of two beautiful Campanian vases that are in the Museum of Geology. Fig. 452 was found at Nola. Fig. 453, from the same collection, is a no less excellent example of a Campanian ribbed vase, of about two hundred years before CHRIST. It was turned on the lathe; the body is red and the glaze black. The ornament on the neck is in engobe over the glaze, and in part incised through the glaze. Among the shapes particularly local at Nola is a species of *œnochoë*, modelled in the form of a

head generally, but not always, that of a female. Vases of Nolan fabric are found distributed through-

FIG. 451.

out Campania. The vases of Pæstum have pale red figures on a black ground, with a dull varnish. They

are of a late period, but singularly good as examples of the age to which they belong. Still further South, the region now called the *Basilicata* has pro-

Fig. 452.

duced an abundant store of vases, which illustrate in a significant manner the decadence of Greek art. Here

Fig. 453.

and there specimens are found of such rich and superior character, that they are undoubtedly importations from Greece itself, and several styles or gradations of style may be observed in the genuine Basilican vases; but the prevailing characteristics of these vases, in addition to the general inferiority of their shapes, are clumsy forms and indistinct representations of figures, crowded with details, and accompanied with most unsatisfactory attempts to render objects in perspective. In these vases the design is drawn in red on a black ground, in the same manner with the examples of a purer period; but the drawing is bad, and the inner markings of the figures are carelessly indicated, and white and red

patches are freely introduced into the accessories; the glaze also has a leaden hue. The subjects are generally Dionysiac and Erotic scenes, and they commonly are treated in a manner altogether inconsistent with that simplicity and dignity which are distinctive characteristics of the highest class of ceramic paintings. The vases found at Ruvo comprehend the finest works of their class that have been discovered in the Basilicata. The Museum of Geology supplies a characteristic specimen of a vase of Ruvo—Fig. 454. It is of an early period, about three hundred and fifty-seven years before CHRIST, and the execution is the same with

that employed in the production of the Campanian vases—Figs. 451 and 452. It is a singular circumstance that in Southern Italy the vases that are

Fig. 454.

discovered are far more frequently found broken into fragments, than in a condition that is even comparatively perfect. The ceramic works produced in Sicily, either by Greek settlers or under Greek influence, differ in no material points from the corresponding remains that are found in Italy; and the Greek vases that have at different times been brought to light along the African coast, with those more recently discovered in the Crimea, appear to have been importations from Athens, or from some other potteries of Greece.

ROMAN POTTERY.—Terra-cotta was used by the Romans from the earliest times of the republic, and also during the era of the kings, for the production of architectural details, accessories, and decorations, as well as for works of statuary. Capitals and bases of columns, corbels, the crests of cornices, the frames of windows and doors, spouts, bas-reliefs for friezes, and almost every variety of object that was employed in Roman architecture, were constantly executed in this material. The most ancient statues of the Romans, with the bas-reliefs and figure-decorations of their temples and other public edifices, were of terra-cotta; and they continued to be thus produced through the agency of the potter, until the extension of the Roman power into Greece disclosed to the conquerors other and still nobler means by which such works could be called into existence. It is worthy of special notice, however, that the introduction both of Greek sculpture, and of sculptors from Greece into Rome, did not supersede the demand for works of great importance executed in terra-cotta. Terra-cotta was also used by sculptors in marble and bronze for their models. A vast number of figures of diminutive size is found throughout the republic to have been made of the same material, and they extend until the middle period of the empire; they comprehend figures of every imaginable class, which were apparently used at the festival of the Sigillaria, or sometimes for other purposes. Having stated that it would be im-

possible to enumerate all the purposes to which the Romans applied terra-cotta, BIRCH observes that some of these are too remarkable to be passed over without special notice; and he proceeds to specify bee-hives, or amphoræ used for hiving bees, that were made by the Romans in terra-cotta, with cones that were heated and placed before other bee-hives in order to burn the butterflies and other insects which attacked the bees; money-boxes also; tesserae, or tickets of admission to the games; moulds from which spurious coins could be forged; toys of every kind; small altars for the sacrifices offered to the Lares; and cages in which dormice were fattened, in order to prepare them for the palates of Roman epicures.

Roman Terra-cotta Vases.—Like the Greeks, and also like the Egyptians before them, the Romans employed vessels of fictile manufacture for every possible purpose connected with their commerce, and with the ordinary requirements of daily life. Vases of terra-cotta were made by them in every variety of shape and size. Specimens of enormous dimensions and capacity were fabricated at all periods, and they were employed as well for storing up figs, honey, corn, oil, wine, and other commodities, as for their transport from place to place. The largest store or transport vases were called *dolia*, and sometimes *cadi*. Amphoræ, having bodies generally more globular than those of Greece, were in constant use for a variety of purposes amongst the Romans; and, like many other Roman fictile productions, they almost always have the name of the maker stamped upon them. The paste of these useful and much-used vessels is coarser than that employed by the Greeks; and it has been observed that until a late period vessels made of the same paste with the amphoræ were used for sepulchral purposes, sometimes as sarcophagi or urns for the reception of the ashes of the dead, and, in some instances, as cases in which more precious vases might be preserved. The vases used for sacrificial purposes, in like manner, were principally of terra-cotta; and so also were the cups and other vessels which, in the case of many classes of the Romans, sufficed for the purposes of the table. The names given by the Romans to their various vases are commonly of Greek origin. Some are Latin, and speak for themselves, and others, and these are not a few, are obscure as well in their distinctive signification as in their origin. As their general characteristic, the Roman potteries must be considered to have produced useful vases, and such as were well adapted to the requirements of life, but which can by no means be regarded as beautiful or fine, and therefore worthy of taking rank amongst works of art. The paste, except in the case of the coral red ware, is much coarser than that employed by the Greeks; but the processes of manufacture were the same, comprising the wheel and all the modifications of modelling, moulding, and stamping. The vessels of very large size, from the necessity of the case, were built upon framework. BROGNIART has classified the terra-cotta pottery of the Romans in the following four groups, distinguished by the color of the vessels:—1, Pale yellow paste, comprising the casks, jars, and amphoræ; 2, Dull red and reddish-brown,

including the pottery of the first century; 3, Grey or ash-colored, which comprehends all Roman pottery of a date later than the first century; and 4, Black, under which division are grouped the Gallo-Roman wares, and those of the provincial potteries. This appears to be the most satisfactory of the many systems that have been proposed for the classification of Roman pottery. In adopting it it will be necessary to observe, that the wares of the different classes are now commonly found together, and they consequently were employed simultaneously by the Romans themselves.

Besides the larger vessels of the yellow ware, there are some subdivisions of this class in which the paste is fine in quality, and of either a rosy or a very white hue, and sometimes intermixed with grains of quartz. The vases formed of this paste are small, and of a superior order as ceramic works. The largest and most comprehensive class of Roman pottery is the second, which comprises nearly all the vessels used for domestic purposes. This red ware varies in color from a pale salmon hue to a deep coral, and in quality from a coarse and gritty compound to a fine compact paste. Grains of quartz and mica are occasionally found intermingled with this paste. This ware is generally red externally, and without glaze; but not unfrequently it is covered with an engobe of white pipe-clay, or more rarely with a black coating, susceptible of a good polish from friction. A subdivision of this ware, which has been distinguished as *false Samian*, has the red paste covered with a thin coating of still brighter red, formed from sulphate of iron. The greater number of the vessels that were made of the Roman grey ware were such as would be used in cooking, and consequently would be exposed to the heat of the fire. There is a distinct class of productions of this color, which closely resembles the modern stoneware of Staffordshire; it is heavy and sonorous when struck. The black ware, which was chiefly used for the requirements of the table, is distinguished by the fineness of its paste, and the skill with which the vessels were made; its ornamentation is rude both in style and in execution.

Roman Terra-cotta Lamps, which are found in considerable numbers throughout the regions that once were comprehended within the wide range of the Roman empire, form one of the most interesting products of the Roman potter's art. The greater number are of a red ware; but many are of a pale yellow or white hue, while others are black. The paste also varies considerably in quality, though it very rarely is as fine as that used in the production of their lamps by the Greeks. In form, these lamps are either circular, with a projecting nozzle and a handle, or elliptical or shoe-shaped. Some were placed on stands, others were designed to be suspended, and others again were not intended to require any external appendages. Many specimens have more than one nozzle, and examples are occasionally found in which various capricious shapes have been substituted for those which conform to the established types. Lamps are first mentioned by the Athenian PHERECRATES, who was contemporary with ALEXANDER the Great; but all those lamps that have been discovered in modern times were

evidently made during the imperial age of Rome. They were manufactured from moulds, and variously ornamented with groups of figures, devices, and patterns. Had the Romans of the empire been gifted with a historical taste, their lamps would have contributed in no slight degree to the illustration, both of their personal memoirs and of their national history; but the lampmakers of those times knew well the frivolous character of the purchasers for whom they worked, and therefore they were content to decorate their productions with figures of popular divinities, demi-gods, and heroes, and with representations of incidents, fables, and ornaments such as would be sure to be in harmony

Fig. 455

with the prevailing sentiments of the day. Among the most remarkable examples that have come down to us, are several lamps bearing the devices and monograms adopted by the early Christians, with which may be included one—Fig. 455—upon which is stamped in relief the golden candlestick of Israel, as it appears upon the arch of TITUS. After the Roman manner, in addition to their decorations, these lamps are generally inscribed with the names of the potters and potteries, or with the places where they were made, or with the

Fig. 456.

title of the class or style of the lamps themselves; while other inscriptions refer to the period of their production, or are of a votive character, or they are stamped with the word SAECVL, or SAECVLARIA—as Fig. 456—in reference to the games of the period.

Roman Red Lustrous Pottery.—This peculiar class of fictile productions, commonly known as *Samian* or *Aretine* ware from the celebrated potteries of Samos and Aretium, now Arezzo, in Tuscany, appears to have been in universal use wherever the Roman arms and the Roman name were known in the ancient world, numerous remains of it having been discovered in every

region in which the Roman people had settled after their conquests. The period of its manufacture is considered to extend from the first to the third century of this era; and it would appear to have been produced in large quantities, as well in Roman Gaul and Germany, as in Italy and at Samos. There is no evidence to show that the Samian was ever manufactured in this island, though its remains are sufficiently common, and especially at the more important Roman stations in Britain. It was apparently imported into this country, as it might have been into many other parts of the empire. The paste is of a rich sealing-wax red color, and well worked before it was wrought into vessels of various forms; BROGNIART, indeed, considers that it was worked in the most perfect manner, and with the aid of the greater part of the processes and means now employed in the most perfect manufacture. The vessels vary considerably in form, but are rarely of a large size. They are thin and delicate in their structure, and it may be inferred that they were considered valuable in ancient times from the fact of fragments being often discovered neatly riveted with lead. The red hue of the body or paste is derived from the sesquioxide of iron; and the brilliant glaze, which appears to have been formed of a silicate with an alkalino-earthly base, is colored red by the same means. Fragments of this ware have given the following analyses:—

	I.	II.	III.
Silica,	54.45	60.67	64.00
Alumina,	22.08	20.96	17.77
Sesquioxide of iron,	7.31	5.95	10.23
Lime,	9.76	6.77	4.86
Magnesia,	1.67	1.22	—
Water,	—	—	2.29
Potassa,	3.22	} alkalies in small quantities.	
Soda,	1.76		

The glaze has been found to consist of 64 silica, and 11.0 sesquioxide of iron. It is remarkable that this ware, wherever it may be discovered, is always exactly identical in its structure, forms, and style of ornamentation.

Across the centre of the bottoms of most Samian vessels are stamped the names of the potters, and they also appear upon the exterior surface of the embossed examples. The vessels themselves are either plain with mouldings, or they have delicate and fine patterns that have been appropriately designated *engine-turned*, or they are embossed with foliage and groups of figures. The scrolls, foliage, and other arabesques which appear on the Samian vessels very commonly, have a decidedly architectural character, and they rarely fail to demonstrate the sound taste of the artists employed in their production. A common form of Samian bowl, with characteristic arabesques moulded in relief, is shown in Fig. 457. The figure designs embrace an almost infinite series of curious and interesting representations of popular subjects which, like those introduced upon their terra-cotta lamps, are strikingly illustrative of the social and religious habits and customs of the Romans. Divinities and their emblems may be reckoned amongst these subjects, with priests and sacrificial ceremonies, bacchanalian processions

and dances, mythic and mythological scenes, fabulous and imaginary animals, other animals more true to nature, shows of gladiators, musicians, and others. The fragment in the British Museum, represented in Fig. 458, is in the highest degree characteristic of

Fig. 457.

Samian ornamentation; the figures are gladiators engaged in combat. Some few examples have the figures modelled in high relief, and affixed to the ware during the process of its production, instead of being moulded upon it. Moulds or materials used in pro-

Fig. 458.

ducing the embossed Samian have been occasionally discovered; they contain the designs impressed upon them in intaglio—as in the fragment—Fig. 459—found near Mayence—by means of a master-mould in relief. Specimens of such master-moulds have also been found;

Fig. 459.

and modelling tools, styles, punches, and other little instruments of ivory and bone, have lingered amidst the

remains of several ancient Samian potteries, as if for the express purpose of telling their tale to the inquiring explorers of modern times. This ware was evidently used much after the same manner that porcelain is at the present day. It is frequently mentioned by PLINY and other Roman writers, with whose words the existing relics are found to correspond with the most satisfactory precision.

Examples have been sometimes discovered in this country, and also in various other places, of glazed Roman pottery of a much paler red than the Samian, and altogether inferior to that celebrated ware. Other rare varieties are grey, yellow, brown, orange, or black; these wares sometimes have a lustrous glaze which shows the color of the paste, and in other examples the glaze has various hues of its own.

Roman Black Lustrous Pottery, made of any tenacious clay in the neighborhood of the manufacturer, varies in its color from a rich deep black to a slate or olive hue. The paste, in many instances, is red, grey, or even white; the black tint of the ware being due to the glaze, which is lustrous and has a metalloid aspect. Many vessels of this class are of small size and simple in form, as in Fig. 460; others are ornamented with incised lines and herring-bone patterns, or with clusters of small studs; and it is also common to find them having their sides depressed in compartments, after the manner shown in Fig. 461. In this example, found in London, the sides are depressed in seven compartments, and there is also a small pattern produced by tool-marks in bands.

Fig. 460.

Fig. 461.

Another mode of ornamentation exhibited in this ware consists of scroll-work, foliage, and hunting scenes, with other figures, executed in low relief upon the vessels after they had left the lathe, by means either of a deposit of semifluid clay, which could be modelled, or by an engobe of white pipeclay. Vessels of this class, though not so generally diffused as the Samian, are found in considerable numbers in all the countries that once were subject to the Roman rule. In this island great quantities have been discovered, which exhibit some varieties of character. The most characteristic examples are from the neighborhood of Castor in Northamptonshire, where Roman kilns for their production also yet remain; this class of Roman pottery has accordingly obtained the title of *Castor ware*. The fragment represented in Fig. 462 is from Castor; and the vase—Fig. 463—which is a most characteristic example, was found at Water Newton, also in Northamptonshire. So perfect are the remains of the Roman kilns, that the different processes employed for firing the wares have been

accurately distinguished; and it has been ascertained that in the case of the black ware, the fire, or rather the smoke of the furnace, was smothered upon the

Fig. 462

Fig. 463.

vessels when in the kiln, and it is supposed that the carbon was thus deposited on the heated surfaces of the vessels, giving them their black glaze. It must be added that occasionally vases have been found which are identical with the black Castor ware, with the sole exception that in color they are of different shades of yellow and yellowish-grey.

CELTIC, ANGLO-SAXON, AND TEUTONIC POTTERY.

—The sepulchral mounds erected over the graves of deceased chieftains of the early European races, have contributed many examples of the vases that were fabricated, both before and after the era of the Roman dominion, in countries beyond the limits of Italy and Greece. The fictile works of the rude and primitive races who inhabited Western and Northern Europe in ages anterior to the spread of the Roman power, are precisely what might have been expected—simple, and, indeed, barbarous in their composition, their forms, their ornamentation, and manufacture. Nor does the civilizing influence of the imperial sway appear to have long survived the decline and fall of the empire; since the pottery which may be assigned to the centuries that immediately succeeded to the era of Roman occupation, exhibit scarcely any higher qualities than those of the primitive period. It is probable, however, that the ceramic relics exhumed from Anglo-Saxon tumuli, and from other sepulchral mounds of the same age, may represent but imperfectly the various kinds of pottery then in use, and particularly such as were employed for domestic purposes. The arts of the Romans, indeed, seem to have passed away almost with the receding steps of the legions; and, on the other hand, it is certain that much yet remains to be accomplished, before the manufactures of the Celtic and Teutonic races can be considered to have been thoroughly investigated. Urns and vases of various sizes and forms, generally without handles, and as commonly inverted as placed erect, are found in Anglo-Saxon tumuli; and, with objects evidently of British or Saxon design, others are occasionally observed which are no less certainly imitations of Roman works. The rudeness of the greater number of the specimens of Anglo-Saxon pottery, is indeed as remarkable as the tendency which it so generally exhibits to assimilate rather to the British than to the Roman types. The paste both of the Celtic and Saxon pottery is coarse, and consists of the clay found on the spot,

and without much preparation, and it has undergone a baking of only a very imperfect kind. The vessels are of a dull blackish-brown hue. They are generally of an urn shape, tapering towards the base, and having wide mouths with bevelled and overlapping lips; and their style of ornament consists for the most part of simple cords or bands of punctured zigzag and herring-bone work, intermixed with dots and small projecting bosses. The two vases represented in Fig. 464, exemplify, in a highly characteristic manner, this class of early pottery. Contemporary fictile works, found at the North of the Tweed, closely resemble the relics of the same class that have been exhumed from barrows in South Britain. The urns and vases discovered in Ireland are also closely analogous to the British; but they are frequently finer in their texture and color, more complex in shape, and more elaborate in ornament. Their general resemblance to basket-work

Fig. 464.

also is more distinct and decided than in the British specimens. In France the Roman dominion has almost obliterated any traces of the primitive Gallo-Celtic potteries, so that a very small number of rude relics of an ante-Roman period has been discovered; and but little more is at present known of the operations of the Gallic potteries during the centuries which succeeded to the Roman sway.

The Teutonic pottery, which is found throughout Germany, bears a considerable resemblance to that of the Anglo-Saxons. The urns are formed of a friable paste composed of clay and sand, intermixed with particles of mica, and the compound varies in color in different localities. Like the Celtic pottery, many of the smaller vases have been modelled by the hand; but some of these, and the greater number of the larger urns, bear decided marks of having been turned upon the wheel. Handles are not uncommon in these vessels. They are ornamented with incised and punctured patterns, or with small bosses, and their decorative accessories are also frequently produced by painting in various colors. In addition to sepulchral urns, vessels have been found in abundance throughout the whole of Germany, of such forms and sizes as denote their original application to various domestic uses. Some few of the smaller works are apparently toys; and others of larger dimensions and still more singular aspect, resemble the hut-shaped cinerary

urns of the ancient Etruscan inhabitants of Alba Longa, and were actually used for sepulchral purposes.

MEDIEVAL POTTERY.—The manufacture of decorative pottery appears to have been unknown in Europe during that dark and stormy period which succeeded the fall of the Western Empire. Throughout these ages, however, there is every reason for believing that such simple fictile vessels as would be required for the ordinary domestic requirements of daily life, were produced by the different European nations. In process of time the potter's art reappeared in Spain, having been carried thither by the Mahomedans when they overthrew the Gothic monarchy in 711. But the influence of the Hispano-Moors did not extend beyond the region which had submitted to their arms, and, consequently, several centuries elapsed during which the ceramic productions of the rest of Europe knew no improvement. And when at last improvements began to be gradually introduced, earthen vessels still continued for a long space of time to be esteemed simply as articles of present utility, so that but few specimens have been preserved, and only casual notices of these objects have found their way into mediæval documents and records. It is known that the Arabs employed lead glaze in the ninth century, and that the Moors introduced their plumbiferous glaze into Spain early in the thirteenth century, about which time its use seems to have spread into other countries. Stanniferous glazes were also brought into Europe by the Hispano-Moors, and probably the use of both tin and lead in glazes or enamels became known in the West at about the same period, though the exact manner and time in which the knowledge of these glazes passed into the different European countries has yet to be determined.

Inlaid Tiles.—There is one class of the fictile productions of the middle ages which claims distinct and special notice. This class comprehends the various decorative tiles that were designed to form pavements, and in some instances to serve as surface-coverings of an ornamental character for walls. For England, in the thirteenth and three following centuries, paving-tiles were produced in great abundance, and in an almost infinite variety. The devices were obtained by impressing or incising the desired designs upon the slabs of dark colored clay, the intaglios being then filled in with a white composition; the surfaces were generally covered with a thick and lustrous glaze, but in some instances the terra-cotta was left without any such protection. The designs that have been observed upon these tiles comprehend geometrical and other patterns, miscellaneous devices, figures, architectural details, heraldry, and inscriptions, and they are invariably both curious and interesting. In some instances the designs are executed in low relief; and occasionally inlaid tiles have been observed that were produced for the purpose of monumental commemoration. A noble pavement of early tile-work has been preserved in the Chapter-house, Westminster; other examples of great excellence remain at Great Malvern, Gloucester, Worcester, and Ely Cathedrals, at St. Alban's Abbey, and in many other churches; but the very finest specimens are those which have very recently been discovered upon the site of Chertsey Abbey in Surrey.

Moulded terra, for architectural purposes, was also produced in great abundance and of excellent character in England, at the same period with the inlaid tiles.

SPANISH POTTERY.—Tiles of enamelled earthenware, called by the Spaniards *Azulejos*, were used for the pavement and the surface-decoration of their buildings by the Arabs wherever they extended their conquests. By the Spanish Moors these beautiful tiles were made in great abundance, and with those examples of them which yet remain, vases and other objects of decorative pottery may be associated. The Moors, indeed, appear to have continued their ceramic manufactures without intermission throughout their partial occupation of Spain, and until their final expulsion about the commencement of the seventeenth century. The colors introduced into the ornamentation of the Hispano-Moorish pottery are rich and gorgeous, abundantly intermixed with gold, yet always adjusted and blended together with judicious taste, and a thorough appreciation of harmony. The enamel is generally of a yellowish-white, over which an iridescent lustre plays with remarkable splendor. The designs and forms alike indicate their Oriental origin; the former comprise arabesques, scroll-work, flowers, and conventional foliage, with occasional birds and animals; and, in some examples, Spanish shields of arms and Arabic inscriptions. The patterns are infinitely diversified, and elaborate and intricate in the highest degree. Sometimes the Arabic legends appear on Gothic shields, and occasionally there may be seen instances of Christian devices and inscriptions. The tiles are formed of a pale clay, the surface being covered over with an opaque white enamel, upon which the elaborate designs are executed in colors. The celebrated fortress-palace of the Alhambra has supplied the most beautiful examples of the tiles—*azulejos*—of the Hispano-Moors, and also the most remarkable vase of their production that is known to be in existence. Other relics yet remain in different places where the Moors once were powerful; and the art of producing *azulejos*, learned by their ancestors from the Moors, is still practised by the Spaniards of the present day.

ITALIAN POTTERY.—Partly from the fictile productions of the Saracens or Moors, as the Arabs of Europe were called, and in part also from the ceramic manufactures of the Byzantine Greeks, Italy may be considered to have obtained the elementary principles of those processes which she cultivated with such distinguished success during the fifteenth and sixteenth centuries. As early as 527, the Saracens conquered Sicily, and adorned their great mosque at Palermo with colored and enamelled tiles, similar to those of the Alhambra. In this same ninth century the Saracens obtained a footing in Apulia. The island of Majorca somewhat later became a stronghold of the same invaders, and there they systematically carried on their characteristic ceramic manufactures with the utmost vigor. In the year 1115, the Saracen king of Majorca was defeated and slain by the Pisans, after a fierce and protracted struggle, when the Pisan galleys, amongst other spoils and booty, carried specimens of rich Moorish pottery in triumph to their native city. Fictile plates, known as *baccini*, are said to have been

incrusted in the walls of the churches of Pisa, as trophies commemorative of this event; and it is certain that the most ancient Pisan churches, as well as those of other parts of Italy, still retain examples of these *baccini*, which are apparently of Moorish origin. It will be remembered that the Moors themselves employed their enamelled tiles for the decoration of the walls of their edifices, and accordingly a similar treatment of the spoils of the conquered Majorcans would naturally suggest itself to the victorious Pisans; and thus the usage might prevail in Italy of incrusting the walls of churches with *baccini*-plates, discs, or pateræ of fictile ware. In addition to the spoils of the Majorcans, and the works of the Italo-Moors in Apulia, and of their brethren in Sicily, other fictile productions would appear at an early period in Italy in consequence of the gradual recovery of Spain from the Moorish invaders. The conquered Hispano-Moors would frequently settle in Italy, carrying with them their potters' art. So also, without doubt, the never absolutely lost art of the ancient potters would travel to the congenial soil of Italy from Byzantium, as soon as there would appear even a prospect of its receiving a cordial welcome. Indeed, in whatever degree the early mediæval potters of Italy may have been indebted to the Moors, and excited by their admiration for the brilliant prismatic coloring introduced into their fictile works by that remarkable people, the revival of the ceramic art in Italy must be considered to have also received a powerful impulse from the operations of the Byzantine Greeks.

In the thirteenth century Italian pottery claims to have attained to a distinctive character. The course of the succeeding century witnessed a progressive advance. Under the Malatestas, lords of Pesaro, the manufacture assumed a more decorative and artistic aspect, and the peculiar characteristics of the works of the two next centuries may be considered to have been determined. A new process at this period was developed, upon which the subsequent ceramic operations of Italy were based. The red, or other comparatively coarse and dark-colored clay which formed the paste or actual body of the pottery was first fixed, or partly baked, and then, by immersion, it was covered with a thin coating or engobe of a composition formed of oxides of lead and tin, and of a very white earth procured from the territory of Siena; after this the ware was again placed in the kiln to receive its final firing. As the enamel was required to be more hard and white, the proportion of the tin was increased. The overlaying of an opaque white surface upon a colored body of a totally different texture formed a process altogether new, which may be regarded as the basis of the celebrated *Majolica* ware of Italy.

Born about the year 1400, and having his life prolonged until 1481, LUCA DELLA ROBBIA commenced his artistic career under LEONARDO, a goldsmith of Florence, of deservedly high reputation. He soon relinquished the profession of a goldsmith, and devoted himself, in the first instance, to sculpture in stone, and afterwards to modelling in clay. After many experiments, he arrived at the conclusion that an almost endless durability might be imparted to his figures in clay, by

overlaying them with a thick glaze of tin combined with other mineral substances. About the year 1438, LUCA succeeded in discovering an opaque white, highly lustrous stanniferous enamel, which he was the first Italian to apply to terra-cotta. His earliest works are in white on a blue ground; but he subsequently introduced green, maroon-color, yellow, and violet. He appears, however, to have used these colors very sparingly, and to have retained his preference for white and blue. The works of LUCA DELLA ROBBIA, distinguished invariably by their simplicity and purity of style, consist of Madonnas and Scripture subjects, with architectural ornaments and glazed tiles. LUCA was succeeded by his nephew, ANDREA DELLA ROBBIA, with the survivor of whose four sons the production of the Della-Robbia ware may be said to have passed away.

The remarkable class of ceramic productions known as *Majolica* is supposed to have derived its name from Majorca, where the Hispano-Moors had long practised the art of applying a peculiar lustrous enamel to pottery. It may be divided into the productions of four periods:—1. From about 1450 to 1530. The works of this period are distinguished as *Mezza Majolica*. In the earlier examples ornamental devices of a moresque character may commonly be seen, associated with busts and various Italian and mythological figures, and brief explanatory inscriptions. The figures represented upon the *Mezza Majolica* have their outlines traced in blue or black on a white ground, with faintly-tinted draperies: there are no shades or half tints, and the flesh is not colored: the drawing, though tolerably correct, is hard and harsh, and the figures have a flat and lifeless appearance. The whole is covered with a film of metallic glaze or *madre-perla*, that produces a richly-glowing iridescent lustre of a splendor that has never been surpassed. 2. The second period comprehends the ten years included within 1530 and 1540. At this era, instead of arabesque and foliage patterns, with busts and armorial bearings, the *Majolica* artists began to introduce groups of figures into their compositions; they made great improvements also in the art of coloring, and employed half-tints and full-colored draperies. 3. The third period of *Majolica*, in which the art was in its greatest perfection, extends from 1540 to 1560. 4. The fourth period, which extends throughout the decline of the art, may be considered to close about 1610, when true *Majolica* gradually ceased to exist; a species of imitative *Majolica*, however, continued to be made at Venice, Naples, Siena, and Savona, until the middle of the eighteenth century. After the year 1560 the decline of the true *Majolica* was rapid, having been in a great measure occasioned by the introduction of oriental porcelain into Italy. In addition to dishes, plates, and bowls of various sizes, the manufacturers produced statuettes, bas-reliefs, vases, candlesticks, inkstands, water-coolers, and cisterns also, and various other objects in *Majolica*. Artists of the highest celebrity were engaged to furnish designs for the decoration of this ware, and these designs were executed—many of them in relief—by men who might also claim to take rank with artists of no mean order. The engravings of MARC ANTONIO and the

drawings of RAFFAELLE and of his disciples were largely used by the Italian ceramic painters, and hence the Majolica has sometimes been denominated *Raffaelle ware*. The idea, however, that Raffaele himself actually painted the Majolica is proved to be erroneous by the fact, that the finest specimens of the ware were not produced until twenty years after his death. In the sixteenth century classical, historical, and mythological subjects were introduced, and formed a strange medley with the paintings of Scripture subjects which still continued to be very prevalent. In the selection of these various subjects, the Majolica artists were in the habit of adopting those which might be considered peculiarly appropriate to their several works. Vessels to contain water, accordingly, were decorated with representations of such incidents as VENUS rising from the sea, or the catastrophe of PHARAOH. Fruit dishes were painted with vintage and other similar scenes. The actions of DAVID, SOLOMON, CÆSAR, or ALEXANDER, would be set forth on royal services; while those destined for ecclesiastical dignitaries would represent scenes in the lives of MOSES or SAINT PAUL. It was a custom amongst the Italians to interchange presents of specimens of Majolica, which were always painted with subjects appropriate to the occasion. Of these, one class in great favor, called *Amatorii*, consisted of plates and vases, which cavaliers presented to ladies they admired. Portraits of the ladies, accompanied with their names and some complimentary epithet, were generally painted upon *amatorii*. From its first appearance, the Majolica received the most liberal encouragement from the Italian sovereigns. When the lordship of Pesaro passed in 1450 from the house of MALATESTA to that of SFORZA, the new rulers at once granted special privileges to the manufactories of Majolica. At Urbino, Majolica flourished under Dukes FEDERIGO and GUIDOBALDO, who severally reigned from 1444 to 1482, and from 1482 to 1538. Both of these princes were invested with the order of the Garter of England, the former in 1474, and the latter in 1503. To GUIDOBALDO, his sister's son, FRANCESCO MARIA DELLA ROVERE succeeded, under which energetic prince the ceramic productions of his country made rapid and most important advances. His son and successor, GUIDOBALDO II., who reigned from 1538 till 1674, witnessed both the crowning perfection and the incipient decline of the art, with which his name will ever be associated. The early *Mezza Majolica* was chiefly made at Pesaro. An artist, who flourished there about 1480, and who employed peculiarly brilliant ruby and golden yellow pigments, was the most remarkable ceramist of the period; his productions, readily distinguished by their peculiarities of treatment, as well as by their singular excellence, are always resplendent with the *madre-perla* glaze. The wares of Gubbio are also celebrated for their iridescent lustre; and the metallic glaze having a ruby color is peculiar to the productions of that city, in common with those of Pesaro. The great artist of Gubbio was MAESTRO GIORGIA ANDREOLI, the brilliancy of whose metallic colors is unrivalled. He delighted in the use of the ruby lustre; and, in addition to golden and silver hues of the same iridescent character, he introduced

an intermediate tint, which has the peculiar glow of burnished copper. It has been observed that the ruby lustre of this artist is transparent, and that when he desired to render it very deep and rich, he first placed blue beneath it. His pieces date from 1519 to 1537. The Majolica of Urbino comprehends a considerable portion of the specimens that still exist, and it ranges from the concluding quarter of the fifteenth century till the decline of the style had been far advanced. These works are in great variety, and they exhibit all the peculiarities, and also all the most excellent qualities of this remarkable class of ceramic productions. The most celebrated artists who painted the Majolica of Urbino were FRANCESCO XANTO AVELLI, whose works are not dated later than 1540, and ORAZIO FONTANA, the date of whose pieces is from 1540 to about 1560. The manufactories of Urbino also benefited by the services of several other artists of deservedly high reputation. Castel-Durante and Faenza are the other places most celebrated for their Majolica, which yet remain to be specified. But little is known respecting the artists who painted at these cities, but their productions may be grouped with the best Majolica of Urbino. Besides its Majolica, Faenza produced bas-reliefs, after the manner of LUCA DELLA ROBBIA; and this city, with Florence, was the first to adopt the beautiful white tin glaze, when the secret of its production had become known some years after the death of LUCA. The term *Fayence*, now generally applied to all enamelled earthenware, and particularly to that of Italy, is supposed to have been derived from Faenza, in commemoration of the early use at that city, in its ceramic works, of the white Della-Robbian glaze. In several cities of the papal states, Majolica was made during the best periods of the art; and subsequently, at the close of the sixteenth century and throughout the century following, and even later still, the same manufacture was actively carried on in several parts of Italy. The artistic character of the Majolica ware rarely fails to produce a powerful impression upon all who may have opportunities for observing it; at the same time, it is no less evident, that both the forms of the greater number of the pieces of this ware, and the nature of their decorations, are such as to render them objects, not of utility, but simply of decoration. In this respect the Majolica differs essentially from the finest vases of the Greeks, in which a useful application of the vessel always predominated over its artistic adornments. The Italian ceramic artists, on the contrary, treated their Majolica as a vehicle for the display of their paintings; and they, accordingly, aimed rather at the production of pictures upon clay, than at the decoration of the various useful productions of fictile art manufacture. It must be added, that Majolica was produced in the sixteenth century both in Germany and France. HIRSCHVÖGEL, an artist of Nuremberg, when travelling in Italy, visited Urbino in 1503; and, having there learned the art of making this ware, he established a manufactory in his native city on his return: his works are ornamented in relief. At Nevers in France also, a manufacture of Majolica was established by Duke LOUIS GONZAGA, about the year 1570, attempts having been already made to produce

the Italian ware at that city by CATHERINE de Medicis. That princess, herself a daughter of a Duke of Urbino, very naturally sought to introduce into France the characteristic production of her native country. It is remarkable that CATHERINE styled the Majolica *Fayence*. MARRYAT states, that it is difficult to distinguish the early works, produced under Duke LOUIS GONZAGA at Nevers, from the true Italian Majolica; and, indeed, it is probable, that the two classes of this ware may be almost identical.

FRENCH POTTERY.—In addition to the Majolica of Nevers, manufactories for the production of enamelled pottery existed at an early period in several cities of France. The ware of Beauvais was honorably distinguished as early as the twelfth century, and it continued to enjoy an increasing reputation during the four succeeding centuries. In the sixteenth and seventeenth centuries Avignon had ceramic works of some importance; and there were also other establishments of the same order in various parts of the South of France. Rouen possessed a manufactory founded by FRANCIS I., which in the seventeenth century was much celebrated. At the same period the productions of Nevers and of St. Cloud were held in high esteem. They were all enamelled, and they exhibit many qualities that still command admiration; but they were altogether deficient in that one quality—originality both in form and decoration—which in so eminent a degree distinguished the works that next claim attention. These are the *Fayence* of BERNARD PALISSY, who was born about 1500 at La Chapelle Biron, in Perigord. Of the humblest origin, this ardent, enterprising, resolute, and persevering man, whose history forms a genuine romance, rose to become an artist, an author, and a philosopher of the highest order. About the year 1550 PALISSY discovered the enamels which enabled him to execute the remarkable ceramic works that are identified with his name. He had labored through a memorable probation of fifteen years before success crowned his experiments. Thenceforward his career as an artist was one sustained triumph. He composed rustic pieces, or dishes, and other objects, ornamented with fishes, shells, plants, insects, and reptiles, all executed in high relief, and perfectly true to nature in both form and color. He modelled exclusively from the fish of the Seine, from the fossil shells of the Paris basin, and from other natural objects found in the same localities. His enamels are hard and brilliant, and his hues rich and vivid; but he did not discover the pure white of the early Majolica. He employed a tin glaze, upon which his colored enamels were laid. PALISSY made many large works for decorating fountains, *et cetera*, besides a vast series of smaller productions of every kind to which pottery is applicable. In the year 1589 this venerable and eminent artist fell a victim to the Huguenot persecution, and after his death his art speedily disappeared. His two brothers, or more probably his nephews, continued for some time to produce works somewhat in the manner of BERNARD PALISSY; but they were able to do no more than imitate at a distance the productions of their great relative.

The French *Fayence* of HENRY II., of the seven-

teenth century, is a class of ceramic works which comprises but a small number of pieces, and which flourished but for a short period. No particulars are known respecting either the artists who produced this *Fayence*, or the part of France in which they lived and worked. It is supposed, however, that the manufacture may have been carried on at Thouars in Touraine, and that the *Fayence* was the production of a single artist—probably an Italian, who had been in the first instance educated by some goldsmith of Florence. The period of this *Fayence* is determined by the presence of the insignia of FRANCIS I. upon the earlier specimens; while upon the later and more perfect works there appear the arms of HENRY II., with his device—the three crescents, or his initial H, interlaced with the two Ds of DIANA de Poitiers, Duchesse de Valentinois. The paste is a hard, fine, and very white pipe-clay, which did not require to be covered, like the Majolica, with any superficial coating. Upon this, when it had been modelled to the desired form, the decorative enrichments were incised, or perhaps in some instances impressed, the incisions or impressions being subsequently filled in with different coloring substances of yellow, brown, and carnation hues. The designs were drawn and executed with the utmost delicacy; and small detached figures, with various objects, designed after the *renaissance* feeling of the period, and boldly modelled in full relief, completed the ornamentation. Over the whole was laid a thin, transparent glaze of a pale yellow. The examples of this peculiar pottery may be compared to the *niellos* of the preceding century, with accessories of *repoussé* and chased metal work; and they contain some of the most delicate productions of fictile manufacture that are in existence.

GERMAN POTTERY.—Long before the introduction of the manufactory of Majolica into Nuremberg at the commencement of the sixteenth century, many parts of Germany had attained to a high degree of excellence in the practice of the potter's art. Throughout the Northern regions, the manufacture of fictile works was not limited to the production of portable vessels, but the use of moulded and glazed terra-cotta was extended to almost every variety of architectural work. Glazed tiles, also, of great size were produced in the German potteries, and particularly in those of Nuremberg. The German wares partake of the characteristics of Italian pottery in union with the artistic attributes of a Gothic race. The wares of a late period are generally of very elaborate workmanship. They are commonly ornamented with representations of the various animals of the country, and not unfrequently the different pieces are found to have been modelled in the forms of deer, bears, *et cetera*. Upon the Upper Rhine many potteries existed, which, in the beginning of the eighteenth century were converted into porcelain establishments. A fine enamelled ware was also made at Cologne, and colored enamelled wares were produced in Lower Saxony. Manufactories of a species of Majolica are said to have been established in various towns of Hungary, Transylvania, and Austria Proper.

DUTCH AND FLEMISH POTTERY.—Delft and the adjacent towns of Holland, were celebrated at an early

period for their fictile wares. These productions were imported into England as early as the reign of HENRY IV.; and, with other Dutch pottery, tiles remarkable for the beauty of both their color and their glaze were brought in great numbers into this country. Paving-tiles of green, yellow, and white, were imported from Flanders in the time of HENRY VIII. for Hampton Court, and for Christ Church, Oxford. Lord BACON introduced others of a similar character at his mansion of Gorhambury, near St. Albans. About the year 1625 these tiles became fashionable, and their use was very general in England. As the sixteenth century drew towards its close, the ceramic productions of Delft acquired a European celebrity, and the success which attended the manufacture of them may be pronounced unexampled. The objects themselves were for the most part closely copied, both in form and color, from the old porcelain of Japan, with which the Dutch were familiar long before it was known to the rest of Europe. The clay found in the vicinity of Maestricht was mixed with marl or sand; and this was covered with a beautiful glaze having a blue tinge, which presented a smooth and even surface, and received paintings, chiefly in blue, in imitation of the Oriental, without impairing the distinctness of the colors. One curious branch of the Delft manufacture consisted of dinner services, of which the dishes and covers were made in the forms, and painted to resemble animals, birds, and vegetables, such as are usually served at table. The pseudo-Japan Delft ware flourished until the commencement of the eighteenth century, when it began to decline. The superiority of the wares of WEDGWOOD caused the Delft to be superseded, even in Holland, by pottery of English production.

Stone-Ware—Grès Cérame—is a densely-baked earthenware, formed of clay mixed with sand, and glazed with salt. It exhibits, when broken, a close grey texture; it is somewhat vitreous, resists the action of fire, and is impermeable to liquids, even such as are of the most penetrating and corrosive nature. The stoneware of the Low Countries may be divided into common and fine. Both are commonly ornamented with subjects in relief, and colored; but the fine stoneware is distinguished by a more elaborate ornamentation as well as by the superior quality of its paste. The common stoneware appears to have been in general use towards the close of the sixteenth century. The specimens of it which are usually found in England consist of stone flasks, having a grotesque bearded mask on the neck, and some device on the body of the vessel. They are known as *greybeards* or *Bellarmines*, the latter name having been given to them in the reign of JAMES I., in derision of Cardinal BELLARMIN, and as an implied compliment to the king. The earliest examples of this ware are of a white-yellowish color, without any glaze, and delicately ornamented with Scriptural or allegorical subjects, produced in relief from copper moulds. This manufacture was indebted in a great measure for its early success to the attention bestowed upon the production of it by JACQUELINE, Countess of Hainault and Holland, the repudiated wife of HUMPHREY, Duke of Gloucester, after her abdication and

retirement in 1433. The later wares have a brown or reddish color, in place of the earlier yellow tint. The stoneware jugs of the same period have various ornaments in relief, including figures, armorial bearings, personal devices, with foliage and patterns, and also with dates and occasional brief inscriptions. Their enamel is hard, and of a rich brilliancy. The Flemish stoneware, or *Grès Flamand*, is peculiarly striking in appearance from its beautiful blue color—commonly used in combination with grey tints—its quaint forms, and rich ornaments. The manufacture of *Grès Flamand* extended from 1540 to 1620, when it gave way before the introduction of oriental porcelain.

ENGLISH POTTERY.—The few specimens of early pottery that have been found in England, and which may be considered to have been of home manufacture, are such as lead to the conclusion that before the seventeenth century this country was chiefly supplied with fictile productions from foreign establishments. In some few instances foreign workmen appear to have settled in England, and thus their art became naturalized with them. Vessels, most of them tall and slender jugs, have been discovered in excavations in London, which may be assigned to the fourteenth and fifteenth centuries, and were probably made in this country. Occasionally, also, other relics have been brought to light, the most curious being some terracotta models for stamping his wares, which had been used by a potter of the time of EDWARD III., and which were found, with numerous fragments, near the remains of a kiln at Lincoln. The glaze used was obtained from lead. Amongst the productions of the seventeenth century, an English Delft may be considered to have occupied a prominent position; dishes, plates, mugs, wine-pots, and other objects were made in considerable numbers at Lambeth, Fulham, Liverpool, and in Staffordshire, the process having been in the first instance introduced at those places by Dutch potters who had settled there. The wine-pots are globular in form, with narrow necks and handles; their color is white; and they are inscribed in blue with the words, *sack, claret, whit*, usually accompanied by dates ranging from 1642 to 1659. A stoneware, identical in character with that of Flanders, was also produced in England in the reign of ELIZABETH, who made many efforts to establish potteries amongst her subjects; but little of importance, however, was accomplished until the close of the seventeenth century.

THE STAFFORDSHIRE POTTERIES, which now produce the great mass of the earthenware manufactured in this country, from their great local advantages have been intimately associated, from a remote period, with the art that has given to them their name. This district contains twelve lordships and three parishes, and now constitutes the borough of Stoke-upon-Trent. There the Romano-British ceramists plied their wheels and threw their clay. There the Saxon *tile-wrights* practised their useful calling, and transmitted to the Norman potters a hereditary craft. English potters now flourish in the same localities, and, in memory of long-past times, they still have amongst them a family named TELLWRIGHT—formerly written TYLRIGHT—who for several centuries have been settled in Burslem,

and are in all probability descended from a remote ancestry who exercised what our Saxon forefathers—before the Normans had introduced the word *potta*—designated the *tile-wrights'* occupation. In the year 1686, Dr. ROBERT PLOT, in his Natural History of Staffordshire, first directed public attention to the potteries of that county. He mentions Burslem as being the seat of the most important pottery of the district, and he also speaks of the manufacture of tobacco-pipes at Newcastle-under-Lyne. He gives a minutely exact description of four varieties of white and red clays, all of them found within half a mile of Burslem, the best being dug up nearest the coal, which were of close texture and would work well on the wheel; and three other clays of looser and more friable natures, called *slips*, which were used for painting the wares. One considerable branch of the Burslem pottery manufactures at that time consisted of butter-pots—coarse cylindrical jars to contain butter for sale. An act of parliament passed in 1661, provided that these butter-pots should not exceed six pounds in weight, and should contain at least fourteen pounds of butter. Tygs or tiggs, drinking-cups, commonly having two or three handles, were made at Burslem, in addition to the butter-pots, both before and during the reign of ELIZABETH, and specimens of them are the earliest examples of Staffordshire pottery that are known to be in existence. The tyg was a kind of loving cup, and had its handles so arranged that two or more persons drinking out of it, and each holding a separate handle, might bring their lips to different parts of the rim. Ornamented dishes appear to have been made at Burslem as early as 1650. Until 1680, a lead glazing was employed; glazing by means of salt was accidentally discovered in that year, and first used by a potter named PALMER. About 1605, white and brown stonewares were made by THOMAS MILES of Skelton. These wares, when salt-glazed, were called *crouch-ware* by the Burslem manufacturers, who first produced them in 1690. The vapor arising from the salt-glazing is described as being so considerable, from about eight to twelve o'clock on Saturday mornings in the town of Burslem, as to produce a dense white cloud, sometimes so thick as to cause persons to run against each other in the street. At that period—1700—Burslem contained twenty-two ovens, each having eight mouths at equal distances. In 1852 it was estimated that upwards of sixty thousand persons were regularly employed in the hundred and thirty-three fictile establishments then in active operation in the Staffordshire potteries.

The first attempts that were made to imitate some Japan ware by the Staffordshire potters were not successful; but in 1690, two brothers named ELSERS from Nuremberg, discovered a bed of fine compact red clay, which enabled them to produce with complete success a fictitious Japan ware. The discovery of the use of calcined and pounded flint as an ingredient in pottery, attributed to the younger ASTBURY in 1720, led to great and highly important improvements in the Staffordshire wares. The new material was used in combination with pipeclay and sand, and colored with oxide of copper and manganese. The agate and tortoiseshell wares, some of the specimens being moulded

in relief and enriched with gilding, were thus produced. About this time moulds of plaster of Paris were introduced from France into England by RALPH DANIEL of Cobridge, and generally adopted by the English potters. The wares produced from these moulds were distinguished only by their different shades of color, and were known as drab, or cream-colored, and white. Printed and painted wares also soon followed the plain varieties. The forms and patterns of this pottery were generally obtained from the silver plate of the period. Such was the condition of the English pottery manufacture in the most important district in the country, when another PALISSY arose in England in the person of JOSIAH WEDGWOOD.

In common with several members of his family, THOMAS WEDGWOOD had carried on the manufacture of pottery for some years at Burslem, at the time of the birth of this son JOSIAH—the youngest of thirteen—in 1730. Very scanty was the education which the young JOSIAH was enabled to acquire, and very early in life he found it necessary to work as a thrower in his elder brother's pottery. His weak health compelled him to relinquish the more laborious occupations of his art, and to follow the natural inclination of his ingenious and enterprising mind. He made various ornamental and useful articles in clay, mixed with metallic oxides, and thus obtained imitations of jaspers, agates, and other variegated stones. In 1759 he succeeded in fabricating a white stoneware, and subsequently a cream-colored ware, by which he gained a high celebrity. This renowned ware was composed of the whitest clays of Devon and Dorset, mixed with ground flint, and covered with a brilliant vitreous glaze. It was capable of enduring sudden and violent changes of temperature, and was not affected by acids. Some specimens having been presented to Queen CHARLOTTE, WEDGWOOD was appointed the royal potter, and his cream-colored pottery he was desired thenceforth to designate *Queen's-ware*. His success having now become established, WEDGWOOD applied himself with the most devoted assiduity to the introduction of various improvements in the composition, glaze, and color of his productions. He consulted the writings of the best authors who had treated of chemistry; he worked assiduously at his own experiments; and he sought the aid and co-operation of the ablest workmen and the most accomplished artists. Having completed his most interesting discoveries, in 1763 WEDGWOOD opened a metropolitan establishment in St. James' Square, in connection with his friend BENTLEY, a descendant of the celebrated critic. Having obtained the loan of valuable specimens of antique sculpture, cameos, intaglios, seals, and other objects, WEDGWOOD produced the most admirable copies of them in his new wares. Amongst the most remarkable of his reproductions, are the fifty copies which he made in his peculiar pottery of the Barberini, now the Portland, vase. The Wedgwood Portland vases are examples of the *Jasper pottery* of this great artist. This remarkable class of fictile works was produced from a white body of extraordinary delicacy and beauty, which, unlike any other ceramic composition known either in ancient or modern times, possesses the property of receiving through its whole substance, from

the admixture of metallic oxides, the same colors that those oxides communicate to glass or enamel in fusion. The effect of this property was such as enabled WEDGWOOD to produce, in bas-relief, any figures or objects that he might desire, of the purest white upon colored grounds. The blue jasper of his grounds he obtained by adding to the mixture of his vitrescent materials oxide of cobalt, the quantity being increased as a greater depth of color was desired. In the case of the green jasper, the admixture was made with the protoxide of chrome. So great was the extent to which the manufacture of imitative gems was carried by this process, that the catalogue of *Antique Ornaments, et cetera*, published by WEDGWOOD in 1777, enumerates and describes seventeen hundred and thirty-five cameos, and three hundred and sixty-six intaglios, which had been reproduced by him in fac-simile from ancient works. Another important discovery made by WEDGWOOD, was that of painting on vases and other objects without the glossy appearance of ordinary paintings on earthenwares—an art practised by the ancient Etruscans, but which appears to have been lost since the days of PLINY. It is worthy of especial record that, in addition to his vast series of objects of an exclusively decorative character, WEDGWOOD also produced many articles of domestic use and requirement, all of them designed in the same true artistic spirit, modelled with the same care, and adorned with the same admirable bassi relievi, as his more elaborate and costly works. The fame of WEDGWOOD was so great that his works at Burslem, and subsequently at Etruria, a village erected by him, and to which he removed in 1771, became a point of attraction to visitors from all parts of Europe; while his own talent and energy, coupled with the sound judgment which led him to secure the co-operation of such an artist as FLAXMAN, not only obtained for him extensive patronage and an ample fortune, but also greatly promoted the commercial interests, and exalted the reputation of his country. He died in his sixty-fifth year at Etruria, January 3, 1795. During his lifetime, WEDGWOOD sold his ware at a price which brought it within the means of general consumption, both at home and abroad; and so highly were his works prized on the continent of Europe, that, notwithstanding duties that were intended to prohibit the admission of British earthenware, not less than five-sixths of the entire quantity which he made were exported. His cameos and other works are still held in high honor abroad, and at home Wedgwood-ware of every description now finds ready purchasers at prices which significantly indicate its present reputation. It is most satisfactory to be able to add, that the influence of JOSIAH WEDGWOOD has acted most beneficially in promoting the permanent improvement of British pottery, and also that the wares which still issue from Etruria are not unworthy of their association with his name and his memory.

In the seventeenth and eighteenth centuries manufactories of pottery existed, and flourished with varying success, at Lambeth, Fulham, Liverpool and its neighborhood, Leeds, York, Bristol, Nottingham, Jackfield in Shropshire, and Lowestoff in Suffolk. The potteries of Lambeth and Fulham produced a species of delft

and a stoneware, with some excellent decorative tiles. At Lambeth the manufacture of stoneware is still carried on to a great extent; the materials are pipeclay from Dorsetshire, pulverized Staffordshire flint, and sand; a salt glaze is used, which renders the ware perfectly impermeable to water, and even to acids. The Liverpool manufactories produced many fictile works of considerable interest and importance. They are first mentioned in the year 1674. A century later, SADLER and GREEN introduced the art of printing upon pottery; and they succeeded so completely in keeping their process secret that, until the time of his death, WEDGWOOD was in the habit of sending his Queen's-ware to Liverpool to be decorated by the new style of ornamentation, after which it was returned to Burslem and Etruria. In 1752 RICHARD CHAFFERS made a fine white earthenware at Liverpool; but finding WEDGWOOD a formidable rival, he directed his attention exclusively to the production of porcelain. After many disappointments, he succeeded in discovering accidentally the requisite materials, and he produced a chinaware of great excellence. About 1760 the manufactory of PENNINGTON at Liverpool became celebrated for punch-bowls and vases of delft. PENNINGTON was also noted for his wonderfully successful imitations of Oriental porcelain. He eventually broke up his Liverpool establishment, and retired to Worcester.

At the present day the potteries of Staffordshire and of other parts of England occupy a most important position amongst the national industries. Every imaginable object that may be produced from clay is now made by English ceramists, and the most elaborate and the simplest works are executed with equal facility and the same success. The early fictile productions of the country, *inlaid tiles* and *moulded architectural terra-cotta*, have been revived, and are now produced with admirable skill. His inlaid tiles were the productions which in a pre-eminent degree established the fame of HERBERT MINTON, a man whose name will ever be honorably remembered as one of the worthiest of ceramic art manufacturers. Messrs. MAW are more particularly distinguished for their tiles having geometrical designs, after the manner of the ancient tessellated pavements; and PULHAM of Broxbourne, in Hertfordshire, may be specified as taking the lead amongst the most successful producers of moulded terra-cotta.

MEXICAN AND SOUTH AMERICAN POTTERY.—Examples of several varieties of ancient pottery have been discovered in Mexico, and described by STEPHENS in his *Incidents of Travel*. They have been obtained from the ancient tombs of the country, and are remarkable for their singularly grotesque forms rather than for any other distinctive peculiarities; the fictile works of Mexico, however, at the time of the invasion by the Spaniards, are spoken of by the conquerors in terms of great admiration. The early pottery of Peru, Chili, and Columbia has a peculiar character which very decidedly distinguishes it from any European, and also from all Oriental works of the same class. It approximates to the Mexican, having the same uncouth and rude forms, and a similar grotesqueness pervading its ornamentation; and yet in connection with such indi-

cations of a rude condition of manufacture, many of these works exhibit in their carved or impressed decorations, patterns identical with such well-known classic forms as the Greek honeysuckle, the frette, and the Vitruvian-scroll. In his History of Brazil, alluding to the excellence of the South American potters, SOUTHEY states that the Tupinambas were in many respects an improved race. The women were skilful potters, they dried their vessels in the sun, then inverted them, and covered them with dry bark to which they set fire, and thus baked them sufficiently. There were some who buried their dead in jars large enough to receive them erect. The Tupinambas, by means of some white liquid, glazed the inside of their vessels so well that it was said the potters in France could not do it better, but the outside was generally finished with less care. Fig. 465 represents a chief of the Coroados

Fig. 465.

Indians in his funeral jar, decked with his war ornaments and his arms, sitting on his heels in the usual posture of the savage in repose, and having some animal at his feet. Such sepulchral deposits are found at the foot of the large trees of the forests.

It is far from improbable that future researches may bring to light many varieties of pottery, some of them perhaps the simple and rude productions of aboriginal races, in regions which now can scarcely be said to have supplied any contributions to the history of fictile manufactures; and possibly, also, the sepulchres of long-departed generations may yet contain an abundant store of precious examples of ceramic art, scarcely less interesting than the most esteemed of those that are so well known, and which, at the same time, may prove to be distinguished by characteristic qualities peculiarly their own.

EUROPEAN PORCELAIN.—Although vases and other pieces of Chinese porcelain had found their way into Europe before the Portuguese doubled the Cape of Good Hope in 1497, it was not until after that event that this porcelain became well known to the various European nations. Having introduced comparative large quantities of Chinese porcelain into Europe about the year 1520, the Portuguese were succeeded in a great part of their East Indian traffic by the Dutch. The earliest known mention of China in England is in 1586. In 1600 the English East India Company was founded,

and having at length formed an establishment at Gambor in the Persian Gulf, it was enabled to introduce Chinese porcelain directly from that port into England, and hence it became known as Gamborware. In 1631 China was commonly imported into this country.

A familiarity with the porcelain that was brought into Europe from China, naturally induced a strong desire in the minds of European chemists and manufacturers, to produce a ware that was at once so beautiful and of such signal utility. Two centuries, however, had passed away before the most energetic efforts could attain to more than a habit of systematic copying of Chinese forms and patterns, upon the ordinary fictile wares of European production. The translucence that characterised and distinguished the porcelain of the East remained undiscovered until the commencement of the eighteenth century, when BÖTTCHER first succeeded in producing, at Meissen, the true porcelain known as *Dresden China*.

The two chief components of porcelain are entitled *Kaolin* and *pe-tun-tse*. The Kaolin—its name being considered to be derived from Kaon-ling, or Lofty-ridge, the name of a range of hills near the imperial Chinese porcelain works of King-te-chin—is an infusible substance, consisting of alumina or clay, or, in some cases of decomposed felspar; and the pe-tun-tse, or white paste, which is fusible, and produces the translucent quality of the ware, is composed of felspar or petrosilex reduced to powder. The two classes or varieties of porcelain, severally distinguished as *hard paste* and *soft paste*, contain the two principal ingredients in different proportions; the hard contains a greater quantity of alumina and less of silica; in the soft the proportion of silica is increased. The former acquires a greater, and the latter a less density. The latter, also, is soft in two senses; first, as being less able to resist a very high temperature; and, secondly, since the paste, where unprotected by the glaze, is easily scratched by an iron instrument. It must be added, that besides the naturally soft paste—*tendre naturelle*—there is a porcelain formed from a paste that is artificially soft—*tendre artificielle*.

BÖTTCHER was an apothecary's assistant of Berlin, who fled into Saxony to avoid the persecution which threatened him in consequence of his reputation as an alchemist. In 1709 he produced a true white porcelain of sufficient merit to induce the elector, AUGUSTUS II., to establish a manufactory. In the year following, BÖTTCHER was appointed director, and in 1715 he succeeded in making fine porcelain of great excellence. BÖTTCHER used the kaolin of Aue, in the Erzgebirge, and the most profound secrecy was rigidly enforced with respect to the entire process of the manufacture. Notwithstanding every precaution, however, certain workmen escaped from Meissen; and, the secret having thus become in some degree divulged, other porcelain manufacturers arose, one by one, in various parts of Germany, and particularly at *Höchst*, *Fürstenberg*, *Baden*, *Kronenburg*, *Nymphenburg*, and *Fromtrental*. In the year 1720 and 1751, the great establishments of Vienna and Berlin were severally founded, and they speedily obtained for their works the very highest

reputation. The porcelain of Berlin, indeed, rivals that of Dresden.

Meanwhile, in 1713, REAUMUR commenced a series of experiments, based upon the transmission of Chinese kaolin and pe-tun-tse to Paris by D'ENTRECOLLES, which paved the way for the successful use of those substances in the Sèvres manufactory, after they had eventually been discovered in France. Before this discovery, the researches of REAUMUR led to the production of an artificial porcelain from a soft paste—*pâte tendre*—the composition of which was both complicated and costly. Manufactories were established at *Chantilly* and *Vincennes* in 1735 and 1745; and in 1754 the manufacture was transferred, under a special royal sanction, to Sèvres. True kaolin was accidentally discovered in 1768, at *St. Yriex*, near Limoges; and having been ascertained by MACQNER to be both abundant and of good quality, it was introduced at Sèvres, where, in 1769, the production of hard porcelain was regularly established. The two varieties of porcelain, however, continued to be made conjointly at Sèvres until 1804, since which year the hard or true porcelain only has been produced. It is very remarkable that the quarries of *St. Yriex* produce not only the kaolin, but also the pure white felspar or pe-tun-tse which is indispensable in the production of porcelain.

Some degree of uncertainty hangs over the date of the first English porcelain manufactories at *Bow* and *Chelsea*, nor is it distinctly known what were the clays employed in the earlier works at *Derby* and *Worcester*. The natural kaolin of Borey Tracey, Devon, is said to have been worked in 1730; but the kaolin of Cornwall, which caused such great and important improvements in the porcelain manufactures of England, was not discovered by COOKWORTHY until about 1755. Kaolin, or *China-clay*, is now chiefly prepared from the granitic rocks of both Devon and Cornwall; and, as in the instance of *St. Yriex*, pe-tun-tse, called also *China-stone*, is obtained from the same Cornish rocks which also furnish the kaolin. Bone is an ingredient in common use in the composition of English porcelain.

In addition to the porcelain manufactories of Germany, France, and England, there are establishments for the production of this ware at St. Petersburg and Moscow, at Amsterdam and the Hague, at Copenhagen, at Zurich and Nyon in Switzerland, and in several cities and towns of Italy, Spain, and Portugal.

GERMAN PORCELAIN.—*Dresden* is remarkable for the beautiful forms, and the uncombined richness and delicacy of the painted and gilded decorations. Figures of every kind have been made in it at all times, and they are held in very high esteem. The Dresden candelabras have never been equalled by any others. The clock-cases and snuff-boxes, with the porcelain flowers, lace, and the honey-comb, and May-flower vases, are all of great beauty, and exemplify the singular taste and skill of the artists who produced them. The value of this ware is determined by the fashion of the piece and the execution of the paintings, which are generally copies of the works of the best Flemish and Dutch masters. The Dresden porcelain with the royal mark—two words crossed having a dot below them, A.D. 1778—is the most valuable.

Berlin porcelain, which closely resembles that of Dresden, is almost equal to it in form and painting. Berlin is now celebrated for the manufacture of a *lithophares*, or translucent pictures, executed in white porcelain. The porcelain of *Vienna* is thicker than that of Dresden, and its glazing has a grey line. It is distinguished by the excellence of its raised and gilded work, and for the application, in relief, of solid platina and gold. It is now exported in large quantities to Turkey, Russia, and Italy. The *Höchst* porcelain, which was produced in no great quantities from 1740 till 1794, partakes of the beauty and excellence of the Dresden manufacture. In varying degrees, also, the same character may be assigned to all the porcelain produced in other parts of Germany.

FRENCH PORCELAIN.—In France the porcelain manufactures have always enjoyed the highest patronage, and every encouragement has been given to promote their success. The results have fully realized the most aspiring hopes of their friends and admirers. The early soft porcelain of Sèvres is remarkable for its creamy and pearly softness of color, the beauty of its painting, and the depth of its glaze. After repeated efforts the Sèvres artists, who have ever reckoned among their number men of the most distinguished ability, succeeded in producing upon the hard porcelain the most exquisite landscapes, with flowers, and various figures disposed in graceful medallions. Portraits and miniatures were subsequently introduced. The jewelled cups must be specified, as occupying a place of honor in the productions of Sèvres. In form this porcelain is decidedly inferior to the Dresden, but in beauty of painting, richness of gilding, and depth of color, it has never been surpassed. The peculiar ground-colors of the Sèvres porcelain, that so justly enjoy a pre-eminent popularity, are distinguished as *bleu-de-roi*, a rich, deep blue; *bleu-turquoise*, a pale blue, the tint of the jewel; yellow, or *jonquille*, a full, glowing green, or *vert-pré*; and the lovely rose-color, called after Madame Dubarry, *rose-Dubarry*. In connection with the royal porcelain manufactory at Sèvres there is a *Ceramic Museum* of the utmost value and interest, the establishment of which was due to the exertions of the learned and accomplished director of the manufactory, the late M. BRONGNIART. Twenty-one other porcelain manufactories in France, besides that at Sèvres, are noticed by MARRYAT.

ENGLISH PORCELAIN.—About the middle of the eighteenth century the porcelain works of *Chelsea* attained to considerable importance, and under the patronage of GEORGE II., and of the Duke of CUMBERLAND, they produced services, and various pieces and objects of the very highest excellence. The early Chelsea-ware aimed at a close imitation of the Chinese, but subsequently the forms and decorations in favor in France were adopted, and retained in use until the close of the works about 1765. About the same period with the Chelsea, *Bow-china* was made at Stratford-le-Bow, and was generally distinguished by its embossed and quaint devices. When the Bow works were given up, about 1750, a porcelain manufactory was established at *Derby*, which, on the decline of the Chelsea-ware, became celebrated. It is very trans-

lucent, and of fine quality. This porcelain has long ceased to be produced; which is also the case with the beautiful ware, the first true porcelain of hard paste made in England, at *Plymouth*, by COOKWORTHY, and with the *Bristol*-ware, of still superior character, which succeeded it.

In 1751 the manufacture of porcelain was introduced by Dr. WALL, at *Worcester*, and, from the first, the works produced at that city have commanded decided admiration, and secured extensive patronage. The earliest efforts were directed to the imitation of the porcelain of China and Japan. About 1756 the important process of *transfer printing* was discovered and adopted at Worcester. In 1786 GEORGE III. paid a visit to Worcester, when he granted the patent which gave to that city the first *Royal Porcelain Works* in England. At this period, and until the present century had seen its first quarter pass away, the artists of the Worcester establishment appear to have been influenced by an irresistible desire to imitate the most attractive works of other ceramists, and they accordingly studied with equal attention the best productions of Dresden, Berlin, and Sèvres, as well as those of the East. More recently the Worcester porcelain, which has always been celebrated for its beautiful translucency, and the rich variety of its colored and gilded decorations, has gradually assumed a decided and definite character, and it stands in the front rank of the fictile manufactures of England. The present productions of the Worcester works comprise the most exquisite works of ceramic art, together with every variety of useful object—the spirited proprietors are Messrs. KERR and BINNES. Nearly contemporaneous with the works at Worcester are those that still flourish on the right bank of the Severn, at *Coalport* and *Colebrook Dale*, and other places in the same neighborhood in Shropshire, and produce vast quantities of excellent porcelain. The porcelain wares of *Nantgarrow* and *Swansea*, also of about the same date, were amongst the first that succeeded in England in attaining to the highest qualities of the manufacture; and besides these, attempts, attended with various degrees of success, were made in other parts of England, for producing the universally-admired porcelain for which Europe was indebted to the East. At the present day porcelain manufactories, side by side with those for the production of the humbler classes of fictile works in terracotta, are carried on in many parts of England, but Staffordshire and the city of Worcester still continue to be the scenes of the most important operations. Amongst the most distinguished of the Staffordshire manufacturers are the firms of COPELAND, MINTON, and RIDGWAY; and with them the names of ROSE and of BATES must be associated as ceramic manufacturers of the first class.

STATUARY PORCELAIN AND PARIAN.—Under these titles are comprehended some of the most beautiful and most popular productions of modern ceramic art. These delicate compounds were introduced about 1842 by COPELAND, MINTON, and KERR, for the execution of statuettes and other decorative works of a high order; and they have been constantly improved, until they now have attained to the utmost perfection. Delicate and

refined in the highest degree, the Parian or statuary porcelain is eminently sculpturesque in its aspect and tone of color, and at the same time it excites no suspicion of fragility or evanescence. Works thus executed are true works of art, and the comparative facility with which they may be produced renders them easy of general access.

CERAMIC ENAMELS.—The processes for the application of enamels to metals, so famous in the middle ages, have been revived by modern ceramists, and by them used for the decoration of certain classes of their own works. These works are executed on porcelain in the style of the champléré metallic enamels of Limoges, but without their thread-like lines of gold; they exhibit the same beautiful tints with the enamels of the thirteenth and fourteenth centuries, and are uniformly distinguished by an exquisite delicacy of touch and general treatment, associated with admirable energy and decision of expression.

Turning from this historical account of the ceramic art to the modern practice of manufacturing the various kinds of pottery wares, the first thing to be considered is the nature of the *clays* and other substances used in the art.

PROPERTIES OF CLAY.—Clay consists of a hydrated silicate of alumina in combination more or less with other substances derived from the felspathic rocks, which by their disintegration and decomposition have formed the clay; the silicates of potassa and soda, which form constituents of the felspar, having been dissolved out by water during the decay of the rocks. The chemical formula of the more important varieties of clay, according to BROGNIART and others, may be represented by $2 \text{Al}_2\text{O}_3$, 3SiO_2 , 4HO , which appears to be the composition of the fire-clay of the Staffordshire coal measures. In nature, however, the greater number of clays is intermingled with substances foreign to them in their original localities, fragments of undecomposed rock, carbonate of lime, magnesia, and the oxides of iron, certain proportions of potash, and variable amounts of silica in the hydrated condition, all of which modify the character of the clay and its applications, according as one or other of these ingredients predominates.

Pure clay is soft, more or less unctuous to the touch, white and opaque, and when breathed upon emits a characteristic odor; it may be converted by water into a doughy, tenacious, plastic paste, insoluble in water. The most prominent physical properties of clay are its plasticity and behavior when exposed to heat; when slowly dried and exposed to a high temperature, it shrinks considerably, and splits into masses extremely hard, and does not undergo fusion in the furnace; the stronger the heat to which it is exposed, the more dense, sonorous, and hard the clay becomes, although still porous enough to absorb water with avidity. It is, however, a remarkable fact, that while an increase of temperature brings the pores of the clay continually closer together, and the burnt clay increases in density and in hardness, this is not the case with the mass itself—a fact which has been proved by weighing porcelain clay after it has been dried or burnt. Thus, porcelain clay which had been exposed successively to

different temperatures was found to vary in specific weight as follows:—

Temperature of	212°.	334°.	639°.	Cherry red heat.	Lively red heat.	White Heat.	
						Low.	Intense
The cubic inch weighed in powder in grammes	38·58	39·52	40·61	42·17	41·24	39·05	38·74

by which it will be seen that the density of the mass itself attains its maximum at an incipient red heat, and is reduced at a white heat to the same state which it had acquired at 212°. In the commencement the clay loses water as much as 8½ per cent.; after having been dried at 334°, this weight then remains unalterable. But other changes occur at a red heat; the particles of clay are augmented in volume and possess less density; at the same time, however, the interstitial spaces are diminished, and they approach more closely together, giving an increase of density to the whole mass of burnt clay, which is practically observed by a diminution of surface, and technically called the *shrinking* of the clay. It can easily be conceived that this shrinking will be very materially modified and affected by the admixture and proportion of foreign matters possessing other properties—substances which may either be constituted of undecomposed detritus of the rocks which form the basis of the clay, or of others which do not yield clay by decomposition.

Pure clay does not fuse in the most powerful blast-furnaces; it dissolves with difficulty in borax, producing a transparent glass; with carbonate of soda it forms a green glass; if ignited with solution of cobalt, it assumes a blue color. Clay is insoluble either by nitric acid or dilute hydrochloric acid; but boiled with diluted sulphuric acid until the acid begins to evaporate, the alumina is dissolved out, together with a small quantity of silica. By boiling in a solution of carbonate of soda, the quartz, sand, felspar, *et cetera*, frequently mixed with the clay, may be separated. The presence of clay in any soil may be readily distinguished by the absorbent quality which it exhibits; when applied to the tongue or lips in a dry state, it adheres to them strongly, absorbing the saliva from their surface. It is this absorbent property in clay which causes it to retain ammonia in the soil. The ingredients which most affect the character of clay are sand, iron, lime, and magnesia, and its plasticity diminishes in proportion to the amount of any one of these sub-

stances which it contains, as they are not plastic. Sand exercises the most marked effect in this manner; lime somewhat less, and oxide of iron very little. Clay containing sand is said to be *poor*, in contradistinction to *fat* clay.

When clay containing lime or iron is subjected to the action of heat, the silica, alumina, lime, and iron form together a mixture similar to that employed in the manufacture of bottle-glass, melting in the fire with more or less ease, according as it contains much or little of the latter two ingredients. Magnesia exerts less influence upon the character of clay; and the greater the amount of quartz and silica that enter into the composition of the clay, the more difficult it will be of fusion. Clays which contain an excess of iron or lime can be corrected by a large quantity of these ingredients. The fixed or *fireproof* clays are thus distinguished from the *fusible* ones. Those containing iron are either red, yellow, or blue, after firing, according to the quantity of the metallic oxide they contain, and the degree of heat to which they have been subjected. Many kinds of clay are permeated by an organic substance which gives them a blue, bluish-grey, or black color, arising from the presence of coloring matters which are of no practical importance, as the clay when exposed to the influence of fire becomes white.

It is upon the property which clay possesses of being converted by heat into a firm compact mass, no longer influenced by the action of water, that its employment in the preparation of bricks and vessels of various kinds depends; and with a view to this object the different varieties of clay have been classified into *fireproof*, *fusible*, *calcareous*, and *ferruginous*—the calcareous being those which effervesce considerably with acids from containing a large proportion of earthy carbonates, particularly lime, while the ochry or ferruginous clays contain much oxide of iron, and possess a red-brown color.

FIREPROOF CLAYS.—*Kaolin* or *Porcelain earth* is one of the most important materials in the production of porcelain. It is an earthy, pure white, greyish, or milk-white substance, easily pulverized. It occurs in granitic soils rich in felspar, but containing little mica or porphyry. The chief localities of this substance are Sedlitz, near Meissen; Morl, near Halle; Oberzell and Diendorff, near Passau; Saint Yriex, near Limoges, Department Nièvre; Saint Austel in Cornwall; China and Japan. Kaolin burns perfectly white. The subjoined analyses exhibit its composition:—

	Kaolin from					St. Yriex. Berthier.

Granite or *Cornish-stone* is a material also much used in the English potteries, and is brought from Cornwall, where the granite hills are intersected by extensive deposits of this stone. It consists chiefly of quartz and felspar, mica not being entirely absent. This rock—pegmatite—after exposure to the decomposing action of the weather for some time, is one of the chief sources, especially in Cornwall, of the porcelain earth. In Cornish stone, which is brought with the porcelain earth into commerce, the decomposition of the felspar has only proceeded so far as to render the stone easily pulverizable. It consists of kaolin, undecomposed felspar, and quartz.

Dr. LYON PLAYFAIR has made the following analyses of two specimens of kaolin from Bluebarrow, and from Saint Stephens, Cornwall:—

	Bluebarrow.		Saint Stephens.
Silica,	45.52	46.38
Alumina, with trace of oxide of iron,	40.76	38.60
Lime,	2.17	3.47
Potassa, with trace of soda,	1.90	1.77
Magnesia, phosphoric acid, and sulphuric acid,	traces	traces
Water, with a small quantity of organic matter,	9.61	9.08

The China Clay Works at Saint Stephens, Cornwall, are composed of extensive tracts of felspathic rock in a high state of decomposition, twenty feet thick, standing on a declivity. Trenches are formed around spaces of the rock, and strong currents of water directed into them, which carry off the decomposed portion, united with small micaceous particles. These streams are directed into large pits, termed *mica pits*, where the particles are deposited. The pits are fitted with boards, which are raised from time to time as required, and as the mica rises in the pit, the finer particles of clay being held in suspension flow over the boards, and are conveyed by channels into other and deeper reservoirs or tanks of very large dimensions. When these large reservoirs are filled, the washing process is stopped, and the fine clay is allowed to settle, and is removed in the state of slip or thin paste to more shallow drying tanks, surrounding the general reservoir. The latter are about eighteen inches deep, and in these the slip is allowed to remain until it becomes a stiff paste. Cutting tools are then passed through crosswise, and the superfluous water runs off. The mass is afterwards cut into squares, which are placed to dry on a space appropriated for the purpose, and previously sanded to prevent the squares of clay being mixed with extraneous matter. The squares are arranged in the most convenient manner for drying, and sand is

sifted over them. When in a sufficiently hard state, women are employed with sharp triangular scrapers, to remove all the sand with care, and the squares are then ready for shipment. The scrapings are collected, and again passed through the washing process, so that little or no loss of materials can arise.

The clays vary much in quality, some being much more aluminous than others, and, although not so white, yet possessing most valuable qualities, and making very sound wares. Beneath the argillaceous strata lie the Cornish stone, which is harder in texture, and can be quarried in masses ready for shipment.

The clays are generally known by certain marks impressed upon them by the clay merchants, and which serve as a guide to the potters to recognize the several qualities, and adapt them to the uses of their manufacture.

Granite or Cornish-stone clay, previously dried at 212°, was found to consist of—

	1.	2.	3.
Silica,	46.32	46.29	35.65
Alumina,	39.74	40.09	32.50
Protoxide of iron,27	.27	1.65
Lime,36	.50	traces
Magnesia,44	—	—
Water and some alkali,	12.67	12.67	30.05
Loss,	0.20	0.18	0.15
	100.00	100.00	100.00

Specimen, No. 3, was analyzed by RICHARDSON in its unprepared state.

Another substance, nearly allied to kaolin, and which occurs in large quantities at Houscha, near Bayonne, and is often used in the manufacture of porcelain, has been found by BERTHIER to be halloylite, mixed with a product of the decomposition of pegmatite; it forms a connected, tolerably soft, and easily pulverized mass, is of a dull white color and opaque, affording no dough with water, and consequently not plastic. BERTHIER found it, on analysis, to be represented by the formula—

Pipe-clay is of different colors, very tough, exceedingly plastic, and becomes white, or sometimes yellow in the fire, from the presence of a small quantity of iron. It is used in the manufacture of stoneware, clay pipes, earthenware, *et cetera*, and occurs in very considerable quantities. The most generally known localities are on the Lower Rhine; at Cologne and Coblenz, near Halle; in Devonshire and at Stourbridge in England; and at Dreux and Forges-les-Eaux in France. The following analyses show that these clays contain but little iron and foreign earths:—

	Grossalmerode. Forchhammer.	Strasbourg. Berthier.	Stourbridge. Berthier.	Stourbridge. Editor.	Forges-les-Eaux. Berthier.	Coteau de Prairie, N. America, Catlin.

	100.00	100.00	100.00	100.00	100.00	100.00

These analyses, however, give no clue to the nature of the aluminous compound. The proportion of silica in combination with the alumina and the proportion left free not being stated, while the amount of residue not capable of decomposition by the aid of sulphuric acid is only given in one instance, hence the great differences in the relative proportion of the alumina to the silica, which, observing the same order, is as follows:

3:1, 4:1, 3:1, 2:1, 1:1, and 2:1.

In England pipe-clay occurs as a second layer below the sandy clay which is used in making tobacco pipes. This clay, owing to its possessing the property of contracting more than sandy pipe-clay, is not employed in the manufacture of earthenware; its component parts are,—

	Centesimally.
Silica,.....	53·66

Protoxide of iron,.....	1·35
Lime,.....	0·40
Magnesia,.....	trace
Water,.....	12·08
Loss,.....	0·51
	100·00

Pipe-clay also burns white in the fire, and, before the oxyhydrogen blowpipe it melts to a transparent, almost colorless glass.

Potter's clay.—Among the *fusible clays* may be classed *Potter's clay*, generally used for the production of the commoner kinds of clay-ware. It is distinguished from pipe-clay by the presence of a very sensible quantity of iron and some lime, is more easily disseminated through water, and has the same amount of plasticity as pipe-clay. The presence of lime causes it to effervesce slightly with acids. In color it is generally red, or brown-red, sometimes part-colored from the intermixture of various layers; is less homogeneous than pipe-clay; contains a considerable amount of organic remains, fragments of stone and iron pyrites; varies exceedingly according to the locality in which it is found, being sometimes fat, at others poor. The presence of the oxide of iron causes it always to assume a red or yellow hue after burning, and according to the quantities of this ingredient and of lime which it contains, it fuses more or less easily into a dark, vitreous mass or slag. The analysis of potter's clay, from different localities, gives the following results:—

By	Potter's clay from	Silica.	Alumina.	Iron.	Lime,
Aubert,	Provins—D. Seine et Marne—	57	37	4	1·7
Berthier,	Livernon—D. Lot—	61	30	7·6	2·4
Laureat,	Helsingborg,	60	24	7·5	0·5

The relation of the silica to the alumina in these specimens is, therefore, as 5: 3, 2: 1, and 5: 2.

The common potter's clays in England are found in layers or strata lying over each other, each stratum possessing some distinctive property which fits it for a peculiar purpose. That which is called the sandy stiff, or ball-clay, is the upper layer, and from the considerable quantity of silica it contains is used for making salt-glazed ware. On analysis this clay, dried at 212°, will be found to yield:—

Silica,.....	66·68

Protoxide of iron,.....	1·26
Lime,.....	·84
Magnesia,.....	trace
Water,.....	5·14

100·00

Its specific gravity,..... 2·558

Blue Clay, also one of the fusible clays, is considered the best layer of clay in the whole series. In color it is greyish, but burns perfectly white, approaching China-clay in character. When exsiccated at a temperature of 212°, its analysis, according to Mr. HIGGINBOTHAM, gives the following composition:—

Silica,.....	46·38
Alumina,.....	38·04
Protoxide of iron,.....	1·04
Lime,.....	1·20
Magnesia,.....	trace
Water,.....	13·44

100·00

This clay is also called Dorsetshire and Poole clay, Poole being the port of shipment. It is obtained chiefly from the neighborhood of Wareham, and large quantities are shipped annually for Staffordshire and other parts of the United Kingdom.

These mines of clay are very large, extending upwards of seven miles from the port of shipment. The method of getting the clay varies according to the locality, and great trouble and expense are incurred in removing the superincumbent strata of soil, sand, and bituminous matter, which vary from sixty to eighty feet in thickness, the clay lying beneath a fine bed of sand. The heading of the clay is mixed with sand, and formerly was thrown aside as worthless; but of late years this has been extensively used for fire and fancy bricks, and for other ornamental and useful purposes. The bed of clay, once fairly laid open, is worked by cutting out cubical blocks weighing thirty to forty pounds each, with spades adapted to the work; and to facilitate the operation, currents of water are directed into small dams, into which the workmen constantly dip their spades: inspectors are engaged to examine the quality of the clay as it is taken from the beds, and to reject such as is not considered sufficiently good for shipment. The beds vary from three to six feet in thickness, and the latter is considered a profitable depth. The land from which the clay is procured is taken at a nominally low rental, but in consequence of the expense of removal of surface soil, the rental virtually is large. Returns of the quantities of clay raised are made from time to time, according to the terms of the lease. Railways are now in immediate connection with the mines direct to the port of shipment, and the clay is conveyed thence to Runcorn, where the cargoes are discharged, and forwarded by flats or small boats to the various manufactories throughout the district of the Staffordshire potteries.

The export of Poole clay, according to the Poole Custom House returns, reached in 1850, 54,877 tons; in 1851, 69,286 tons; and in 1859, about 102,000 tons. Many other clays of less value are obtained from the Poole bed.

The *Red* or *Brown Clay*, found in great quantities in

the vicinity of Glasgow, is a surface clay, the deep brown color of which results from the presence of a large quantity of sesquioxide of iron. It is in great demand for common black ware, flower-pots, and red bricks, articles which do not require to be exposed to any very high temperature which would fuse them. This clay, by analysis, yields—

Silica,.....	49.44
Alumina,.....	34.26
Protoxide of iron,.....	7.74
Lime,.....	1.48
Water,.....	1.94
Magnesia,.....	5.14
	100.00

An artificial yellow clay is obtained by a mixture together of sandy clay and red clay.

Fire-clay.—Another variety of clay, termed *Marl* or *Fire-clay*, is very abundant, occurring both on the surface and at various depths underground. From the porosity of its substance, it is well adapted to resist high temperatures, and its principal use in the potteries is for making seggars, or vessels for protecting the ware from the flames during firing. Fire-bricks, crucibles, and melting-pots for glass-works are made from this clay. Analysed, it gives the following composition:—

Silica,.....	66.16
Alumina,.....	22.54

A small portion of the lime in the marl is generally in combination with silica.

Loam is the commonest and least pure variety of clay belonging to the more recent alluvial formations; it is less uniform than any of the foregoing varieties—sand, gravel, stones, wood, roots, and all kinds of vegetal remains being mixed up with it in large proportions. The presence of hydrated oxide of iron gives it a yellow, spotted, and veiny color. Lime is also present, but in less quantity than in the marls. It is soft and easily reduced to powder, absorbs water with avidity, and forms with it a soft paste, which is much less plastic and fat than that obtained from pipe or potter's clay. As it occurs almost everywhere, it is the universal material for making bricks.

Ferruginous Clays, amongst which may be classed redde, bole, and ochre. The former two derive their red color from the presence of oxide of iron, the latter its yellow tinge from the hydrate of the same oxide. These varieties are used as pigments, but not for the same purposes as the other clays. From the large

fusible clay, distinguished from potter's-clay by its slight degree of plasticity. It is easily formed into a soft paste with water, and has a strong adhesion to oily matters, upon which depends the cleansing action of this clay upon woollen stuffs. The best clay for fulling cloth should be neither tenacious nor sandy; as in the first case it would not be easily diffused through water, and in the second it would abrade the cloth too much. The principal localities where it is found are in Bedfordshire, Berkshire, Hampshire, and near Nutfield, Ryegate, in Surrey.

CALCAREOUS CLAYS.—*The Marls*, a term which applies to all those deposits containing clay and carbonate of lime, the latter in considerable quantity. These mixtures being mechanical, and comprising all the intermediate formations between the limestone and the clays, are, from the variable quantities of the ingredient, multifarious in character. Those in which lime preponderates are named *Calcareous Marls*; those in which alumina is most abundant, *Aluminous Marls*. In general the marls afford the most fruitful soil for the purposes of agriculture. Aluminous marls are used in the manufacture of several kinds of pottery. They effervesce with acids. They are chiefly found in extensive stratified layers, consisting of a massive, but soft and pulverable substance, presenting an uneven, conchoidal fracture, easily permeable by water, and possessing but little plasticity; in color of a grey passing into brown. Aluminous marl is rarely of a uniform texture throughout, enclosing hard calcareous or silicious nodules; falls easily to pieces by exposure to the air, and is reckoned amongst the most widely diffused varieties of clay. The proportion of its constituents will be seen from the following analyses:—

amount of iron they contain they are sometimes classed with the ores of that metal.

Flint, quartz, silica, or silicic acid— SiO_2 —is found as an amorphous, black or brown colored mass, and occurs with chalk in roundish or irregularly shaped nodules, weighing from a few ounces to several pounds; it contains moisture, an organic substance, and occasionally iron. Whatever its original hue may be, it always burns white, and acts the part of a bleaching material, neutralizing imperceptibly the yellow or greyish color of the clay. In preparation for use, the flints are calcined in upright furnaces, constructed similarly to ordinary lime-kilns. The flint is thus rendered white and disintegrated, splits in all directions, and is sufficiently brittle and soft to admit of being crushed in the stamping mill, and ground under water in the block mill. A description of these processes will be given further on, under *Earthenware*.

CLASSIFICATION.—The production of earthenware from the different kinds of clays is effected by producing the proper form with the aid of the plasticity of

the clay, and afterwards modifying the formed vessels by heat in such a manner that they become no longer soft or flexible, but of a rigid stony consistence, permanently retaining their form, and able to resist the mechanical violence necessarily inflicted upon them by daily use. The quality of such vessels must necessarily vary according to the nature of the clay, the ingredients incorporated with it, the processes of purification, and the degree of heat of the furnace. Such differences are partly recognized by the color, texture, fracture, hardness, solidity, transparency, and chemical constitution of the ware, and partly by the sound produced by tapping. Many clay wares, *bricks and tiles*, have the appearance of being composed of various clays imperfectly mixed together, and containing foreign substances, as stones, *et cetera*. Other kinds again appear of a more homogeneous consistency, but resemble the former in the porous nature of the mass, which is soft, easily scratched, of an earthy fracture, little sonorous, and perfectly opaque. All ordinary pottery and earthenware, both ancient and modern, belong to this class.

There are other wares, again, such as *stoneware*, in which the mass combines a dense structure with considerable hardness, has lost its porosity and the properties connected with it, by the action of the intense heat of the kiln; produces a clear, sharp, ringing sound when struck; is somewhat translucent, with a fracture indicating an incipient fusion.

Porcelain exhibits the same properties—a fusible substance or *flux* being mixed with the clay.

Burnt clay-wares of a porous nature, and even non-porous vessels, to correct the roughness of surface, are generally covered with a vitreous coating or *glaze*, which, when it contains lead, is fusible and soft; when containing no lead, is refractory and hard. This glaze, according to the nature and requirements of the vessel, being laid on in thinner or thicker coats.

It is upon these and similar considerations that the classification of clay-wares is based.

CLASS 1.—Mass uniformly fluxed, dense, cannot be scratched with the knife, finely granular, *translucent*, very sonorous, white, and uniform.

PORCELAIN.—*Tender Porcelain*.—Mass easily fusible.

English.—Flux, bone-ashes—glaze containing lead and borax.

French.—A vitreous mass, containing no clay, with a lead glaze of harder consistence.

Real Porcelain.—Mass difficult of fusion; flux, a refractory glass, composed of silicate of alumina and potassa; glaze of a similar nature, often containing lime.

CLASS 2.—Mass dense, cannot be scratched with the knife, sonorous, finely granular, uniform, exhibiting incipient fusion, scarcely translucent—or only on the edges—white or colored.

STONEWARE.—*Common Stoneware*.—Mass of a reddish grey or bluish color, generally without glaze, a salt glaze only.

Ironstone Ware.—Mass generally white when it contains a flux, and has a lead glaze; artificially colored, also, without glaze.

CLASS 3.—Mass earthy, porous, pretty hard, opaque, texture open, little sonorous.

EARTHENWARE.—*Fine Earthenware*.—Mass white,

hard and sonorous; glaze of crystal, soft, containing lead.

Delft Ware.—Mass finely granular, uniform, more or less tinged yellow; glaze, a soft white or colored enamel.

CLASS 4.—Mass earthy, very porous, opaque, soft, homogeneous texture, always colored.

Ordinary Pottery.—Partly glazed and partly unglazed; the glaze may contain lead or not, but is always easy of fusion, and transparent.

Lustre Ware.—Mass earthy, porous, opaque, very soft; texture not uniform; glaze metallic and not transparent.

CLASS 5.—Mass more or less not uniform, always colored, very soft, porous, and open, little sonorous, and opaque.

Bricks, Tiles, Ornaments.—Sometimes glazed; mass fusible at a high temperature.

Fireproof Stones, Crucibles.—Mass difficult of fusion, or infusible; not glazed.

PORCELAIN.—*Tender Porcelain*.—This appellation has reference not so much to the hardness of the clay, as it has to the feeble resistance offered by this class of wares to the high temperature of the kiln, and the softness of the glaze, compared with true porcelain. It may be classed under two heads:—Natural, or the tender porcelain of England, in which kaolin or China-clay is the basis; and artificial, or the tender porcelain of France, in which the mass is a mixture of different substances, consisting mainly of silica, with alkaline and earthy salts.

English Tender Porcelain.—So named because the manufacture is exclusively confined to this country, local reasons being unfavorable to the production of true porcelain. The chief of these is the want of a cheap material for the construction of the seggars able to stand the firing, the present loss of seggars in Staffordshire being estimated at from eight to ten per cent. at each firing.

The crude materials which enter into the composition of ironstone China are *plastic clay*, *kaolin* or *China-clay*, and *granite* or *Cornish-stone*, with *chalk flints*, and occasionally *steatite* or *soap stone*, which contains magnesia, 44; silica, 44; alumina, 2; iron, 7.3; oxide of manganese, 1.5; oxide of chromium, 1.2, with traces of lime and chlorine—the action of which is said to diminish the contraction of the wares in the furnace. The bones, which are obtained either from native cattle or by importation, may previously have been employed for the extraction of gelatin or glue, or, for the production of ammoniacal salts by dry distillation, or may be used in the form of animal charcoal; but before they are applicable to the present purpose, they must be thoroughly calcined by being heated to redness with free access of air, so as to destroy all their organic constituents and leave only the mineral ash, phosphate of lime, carbonate of lime, and a little magnesia, in the form of a perfectly white substance. The phosphoric acid diffuses itself at a high temperature through all the materials, uniting them into a translucent enamel, which, being less apt to shrink and lose its form than the hard China body, may be baked in larger kilns, and with less risk of loss

to the manufacturer. All these ingredients are ground, suspended in water, and evaporated into the form of paste in the manner to be afterwards described under *True Porcelain* and *Earthenware*. A frit is then prepared, of which the mass is made up with other substances, as follows :—

FRIT.	
Bone,	100
Sand,	90
Pearlash,	7
MASS.	
Burnt bone,	600
Kaolin,	300
Cornish-stone,	360
Frit,	40

or the mass is not fritted in part, but, as in the case of table-ware, mixed all at once, in the following proportions :—

Bone,	450
Cornish-stone,	200
China-clay,	160
Plastic blue clay,	45

Other mixtures for English China-ware may be given as follows :—

Bone,	840

IV.	
Bone,	320
China-clay,	225
Cornish-stone,	230

The bone and flint are sometimes fritted to produce the highest degree of vitrescence, and then mixed up with other ingredients. A little Dorset clay is frequently added for large pieces, as dishes, *et cetera*, to give more ductility in working and greater stability in the fire. In all cases the ware, from the large proportion of clay in the mass and its extreme plasticity, requires to be fired twice. The first firing lasts longest, being of from forty-eight to fifty hours' duration; and the temperature is gradually raised during the whole time, the heat of the kiln, ranging, according to the composition of the ware, from 100° to 110° Wedgwood's pyrometer. It is somewhat singular that this instrument is never used in the potteries, the proper temperature being regulated by small trial pieces of the same material as the goods to be fired. The average quantity of coal consumed at a firing is from ten to twelve tons. When the trial pieces show that the heat is sufficiently raised, the firing is discontinued, the fire and ashpit doors closed, and the whole left to cool during twenty-four or thirty hours. The glaze is then applied to the ware, and the articles undergo a second firing, but neither at so high a temperature nor of so long duration; and in this consists the essential difference between English and foreign

manufacture; abroad the greatest heat being applied to the glazed vessels, and not to the biscuit ware.

GLAZES.—The porosity of ordinary porcelain seems early to have suggested the use of a glaze, or thin glass covering, for the purpose of rendering it impervious to fluids. The composition of such glazes requires to be such, that when they are exposed to the necessary heat, they shall unite with the body or paste; and that in cooling they may not split, crack, or craze, from occupying less volume in their fired state, and their consequent inability to completely cover or envelope the body of the ware underneath. Those most commonly used are flint, quartz, sand, felspar, gypsum or sulphate of lime, carbonate of lime, borax, boracic acid, chloride of sodium, potassa, soda, and oxide of lead. Some glazes are first formed into *frits*, imperfectly vitrified bodies so termed, and afterwards pounded for use.

Colored glazes are made with the addition of nearly pure oxides of manganese, copper, iron, chromium, cobalt, *et cetera*; *opaque glazes* or enamels, by the addition of oxide of tin, or phosphate of lime; for which see *Porcelain True* and *Earthenware*. Some of the ordinary lead glazes for soft porcelain are given below :—

Cornish China-stone,	100
Calcined flint,	60
Carbonate of lime,	25
Cornish kaolin,	10
Soda,	10
Borax,	60
Carbonate of lead,	30

These ingredients are all fritted together with the addition of twenty per cent. carbonate of lead and ten per cent. flint :—

Cornish China-stone,	34
Chalk,	17
Ground flint,	15
Borax,	34
100	

which substances, when fritted and ground together, are mixed with ten per cent. of Cornish-stone and twenty-one per cent. of carbonate of lead. The lead is sometimes omitted from the mixture, and the requisite fluidity of the glaze maintained by an additional quantity of borax :—

Cornish China-stone,	25
Soda,	6

—see *Earthenware and Porcelain*. But the almost entire absence of clay, depriving the mass of plasticity, rendered the operation one of great difficulty and expense, the cohesion between the particles being extremely slight. This defect was partly overcome by the admixture of one-eighth part of soap and glue, or gum tragacanth, which imparted so much tenacity to the composition as enabled the mass either to be formed in gypsum moulds, or turned upon the potter's lathe. The operation of firing was one likewise of considerable risk, from the vitreous nature of the mixture; the prominent portions of the ware being often either fused or so softened by the heat as to lose their shape. Such defects could only be remedied by suitable supports, at a great expenditure both of time and trouble. The first firing, which was of longer duration than in the case of real porcelain, extended over a period of from sixty-five to a hundred hours; the glaze was afterwards applied to the vessels, and fired for a further period of thirty hours. The colors employed in the decoration of this species of porcelain required careful and particular treatment and preparation. In firing, the dishes and wares, instead of being placed in the kiln in a horizontal position, were suspended on pegs in a vertical direction to avoid fracture, which otherwise would have occurred. The point of suspension—a small hole—will be readily discernible on the under side of all Sèvres porcelain, and indicates a remarkable feature in the process of the manufacture.

Foreign Porcelain or China is the finest and most valuable description of ware, distinguished from other wares by the composition of the paste from which it is formed, giving a body of a fine, hard, translucent texture. Great care is exercised in the selection of the materials to give a colorless mass after firing. Two essentially

different constituents enter into its formation, one an infusible, plastic, white clay, called *kaolin*, or China-clay; the other a fusible, non-plastic material, the so-called *flux*, composed of felspar, with the addition of quartz, chalk, and gypsum, which, softening and becoming vitrified in the heat of the porcelain kiln, forms a kind of cement, binding the clay firmly together, and producing a dense, impenetrable, translucent mass, of a uniform texture throughout, and impervious to liquids. The transparency of porcelain arises, therefore, from the clay body becoming saturated with a mass of glassy flux. Under the microscope the two ingredients can be clearly distinguished from each other, the milky mass appearing as a transparent ground, mixed with an opaque substance, composed of minute globules, arranged in a lineal direction, one on the other, as articulated threads or little rods, which are interwoven and cross each other in all directions; the want of absolute transparency in the mass being due to the reflection and refraction of light from the surfaces of these crystals.

The *Glaze*, equally characteristic with the mass, is composed of *felspar*, sometimes mixed with a little gypsum, but with an entire absence of lead or tin ; it is consequently, of the same nature as the flux, and can be brought into the most intimate union with the flux and the mass, securing another essential characteristic of porcelain—the non-separation or peeling of the glaze from the vessel by any outward shock or sudden changes in temperature. The expansive and contractile powers of the glaze being assimilated to that of the body, it is not affected by high temperature, and its surface is less liable to the crazing so often discernible upon other kinds of clay wares. The absence of lead causes the glaze to be very hard, and to resist scratching. The mass for porcelain vessels is composed as follows:—

Preparation of the Material.—Crude kaolin is not sufficiently pure for the purpose of manufacture, being a mixture of real kaolin with undecomposed felspar and particles of quartz, both of which must be separated or finely ground and mixed, to form a uniform substance throughout. This process of washing and suspending in water, which precedes the grinding, is generally undertaken at the porcelain works, though in some cases it is partially effected at the pits.

The decanting or elutriating apparatus consists of three tubs or basins, A, B, C, placed one above the other—Fig. 466—the kaolin being put into the first basin. A, two men thoroughly mix the mass up with water

Fig. 466.

by stirring it with wooden spades or blungers. When every part has been thoroughly elutriated, the mixture is allowed to run off by the removal of a plug along the channel, *a*, situated a few inches above the bottom, into the vat, B, the stones and coarser particles remaining behind, while those carried forward are arrested by the sieve, *b*, leaving only the decanted liquid containing fine sandy particles mixed with real kaolin. After a further stirring, and remaining for a short time at rest, the sand subsides completely to the bottom, the liquid carrying with it only the argillaceous kaolin into the lowest vessel, where it is allowed to deposit completely before the water is drawn off from the finely-divided clay. Sometimes, as at Sèvres, there are six of these filters, at each of which two men are employed, the small particles of wood, straw, and other light bodies, which of themselves would not fall to the bottom, but float, being separated from the mixture or *slip*—a term in pottery technically applied to any preparation of clay in a state of suspension in water—in its passage from

particular kind of sand and crude kaolin. Sometimes machinery is employed instead of manual labor, for the stirring or kneading up of the mass with water. A vat, A—Fig. 467—is furnished with revolving arms, *a' a' a'*, armed with wooden oars or blungers, which, in their revolution through the mass, effect the requisite kneading and mixing, before the liquid is withdrawn into the subsiding vats. The shaft, *c*, carrying the arms, is inclosed in a second hollow shaft, *b*, to protect the mixture from dust and oil.

Chalk from Bougival is a constant addition to the porcelain paste. The chalk contains about ninety-five per cent. carbonate of lime. Its analysis is as follows—

Carbonate of lime,	95.50
Carbonate of magnesia,	0.80
Silica,	0.80
Water,	1.20
Iron, manganese, and alumina,	1.70
	100.00

Fig. 467.

one to another, by passing through hair sieves. This process of decantation supplies a sufficient amount of felspar and quartz in the state of sand, the strong and argillaceous varieties giving each their

Limestones of equal purity may be substituted for the chalk. At Nymphenburg, as in Meissen, fragments of old porcelain are also added, the mixture of which, when allowed to exceed a certain proportion, injures the plasticity of the paste. For the production of the best class of porcelain much depends upon the careful selection of the kaolin and material, the cost of manufacture being the same. With inferior clay the porcelain loses its whiteness, its sonorous ring, and much of its value. Kaolin, to be regarded as of the first quality and suitable for the finest manufacture, should possess a body of a beautiful white color resembling pure milk, entirely free from all foreign substances, however minute, capable of producing stain or blemish in the subsequent processes of manufacture; also the porcelain body formed from it should be easily worked without fear of cracking, neither too fusible nor too argillaceous; for although it may be possible to correct these faults by appropriate mixture, the mass never turns out so satisfactory. Great care must likewise be bestowed upon the uniform incorporation of the ingredients, so that everything of a coarse and massive nature, as felspar, chalk, gypsum, broken porcelain, *et cetera*, be reduced to the finest state of division, and the rejection of all particles of iron, mica, *et cetera*, which sometimes occur, and the

presence of which might impair the whiteness of the china. Mills are, therefore, employed for this purpose. A vertical section of one is given in Fig. 468. Two millstones, *a* and *b*, are inclosed in a

a b, the bearings of which are secured in solid masonry or framework. *c* is a shaft passing through a boss head, *c*, in the axle, *a b*, and carrying with it a strong framework, *E E*, bedded with stone, upon which the

Fig. 468.

Fig. 469.

cylindrical case or framework, *d*, bound together by hoops, the lower one, *b*, being fixed into position by the wedging, *e*, while the upper one, *a*, revolves by motion communicated to it through the shaft, *f*. This shaft is keyed to the stone by means of a metal casting, *g*, let into its upper surface, which receives the coupling arm, *h*, attached to the lower extremity of the shaft, where it is depressed by the lever, *i*. *j* and *k* are two bevil wheels to which motion is given either by steam or water power, the axle of the horizontal wheel, *k*, being hollow and supported by bearings, *l l*. The shaft, *f*, in direct communication with the millstone, passes through this hollow casing, the rotatory motion of which is imparted to it by the spurs of the lever, *i*, when lowered, coupling with those of the arms of the revolving wheel, *k*. In order to guide the material better in a downward direction, the upper stone, *a*, is not perfectly round, but hewn flat on two sides, with two grooves, *m m*, cut opposite to each other. If the pieces of stone are of larger dimensions than these spaces, they will, of necessity, be excluded from the spot where the tituration is effected. They are, therefore, previously taken to the crushing machine, and brought to a uniform size. Fig. 469 represents a

mill-stones revolve and crush the material thrown in. The revolution of this mass is effected by the spur-wheel, *F*, driven by steam or other power. The materials in every case having been ground, and the clay separated from its coarser particles by elutriation in the manner described under *Kaolin*, are in a state of very fine powder, and mixed together in various proportions according to the manufacture. This is effected by mixing the several ingredients, felspar, kaolin, *et cetera*, by measure in a liquid state, the proportion of weight of solid matter contained in a cubic foot of each separate specimen of *slip* having been previously ascertained, and none of the material being allowed to settle down, but each forming a thickish uniform semiliquid mass.

This method of mixing, although more accurate than that of weighing, does not always give the exact proportion required, in consequence of the changeable nature of the kaolin, which contains sometimes more or less silica and alumina, and these, with the variation in the quantities of potash and lime, materially affect the qualities of the paste. The best proportions of the mass have been determined from a mean of several analyses of the best porcelain manufactured at Sèvres between the years 1770-1836; and are found, according to the results of experience, to be as follows:—

Silica,.....	58.0	Lime,.....	4.5
Alumina,.....	34.0	Potassa,.....	3.0

It is, therefore, only necessary to make an analysis of each of the crude materials that are to be mixed together, to ascertain the quantity of silica, alumina, lime, and potassa each contains, in order to obtain the data for calculating how much of each by weight, and consequently by measure in their semifluid state, will be required to obtain the proper mean quantity as nearly as possible in the mass.

It is worthy of remark, however, that artificial proportions are never so satisfactory in their results as the same when occurring in the natural condition of the kaolin.

Every importation of kaolin being chemically a different mixture, the proportions used of it will vary each time; but the mass must always contain the same quantity of elementary constituents, as the following mixtures of 1839 and 1843 will demonstrate :—

Mixture of 1839.		Contains				Mixture of 1843.		Contains			
Composed of		Silica.	Alumina.	Lime.	Potash.	Composed of		Silica.	Alumina.	Lime.	Potash.
73 Decanted kaolin,		38.69	30.66	0.73	1.75	48 Kaolin,.....		30	16.90	0.05	0.96
24 Felspathic sand,		19.27	3.40	—	1.27	48 Felspathic sand,....		28.30	17.04	0.53	2.01
3 Lime.....		—	—	3.77	—	4 Lime,.....		—	—	4.00	—
		57.96	34.06	4.5	3.02			58.03	33.94	4.58	2.97

It is not to be understood that the practice at Sèvres is applicable to all other localities, or that every species of porcelain, possessing the same elementary composition, should exhibit the same properties; for even supposing the composition in one hundred parts to be identical, very much depends upon the nature of the proximate ingredients in the mixture.

The incorporation of the *mass* is effected in large cisterns or tanks under constant stirring, the paste being afterwards so far freed from water as to form a kneadable, dough-like mass. As this cannot be effected by subsidence, in consequence of the heavier felspar particles falling by gravity to the bottom and causing a disintegration of the mass, recourse is had sometimes to ebullition and evaporation, by which constant currents are kept up in the liquid, and any separation of parts is prevented. This process, however, is not well adapted to porcelain mixture, as it impairs its plasticity, and causes it to become, in technical language, *short*. Other methods are, therefore, substituted—one of which consists in drawing off the paste or slip into long shallow troughs, having their bottoms composed of gypsum, the porosity of which absorbs the moisture from the paste. In this process the gypsum beds require to be repeatedly dried by a gentle heat or by the action of air. Latterly, however, the application of gypsum, as a drying agent, has been superseded by direct pressure, either applied mechanically or by means of the atmosphere. In the former case the mixtures are inclosed in sacks of a strong and closely woven texture, the threads being carefully freed from filaments so as not to attach themselves to the paste, and which previous to use have been well soaked in hot linseed oil, giving them more durability and permeability to water. A number of these bags being placed between two boards, pressure is economically applied by means of a long lever loaded upon the long arm, and having the shorter arm placed against one of the boards, so that in this way the pressure may be maintained as long as desirable. A press of this description will prepare for use about thirteen hundred pounds of paste in three hours; and the process, though not more economical, has the

advantage of communicating greater plasticity to the mass.

Another more refined and successful plan, invented by M. L. TALABOT, consists in applying atmospheric pressure under vacuum to extract the water from the mass. Two vessels, or chambers, A A—Fig. 470—are

Fig. 470.

placed in connection with a pipe, B, of about thirty-six feet in length, by the tubes, a a, b b, furnished with stopcocks. The extremity of the pipe, B, is immersed in a reservoir of water, c. If one of the chambers, A, be filled with water by the pipe, F—Fig. 471—the stopcock being opened so as to communicate with the reservoir by the pipe, B, a vertical column of water will be formed of from forty to fifty feet in height, but the atmospheric pressure being only equivalent

to a column of about thirty-four feet, the vessel, A, will discharge its contents, by means of the pipe, into the reservoir, c, and form a vacuum above. The filtering vessels, D, D, placed above and communicating

Fig. 471.

with the reservoirs, A, A, by pipes and stopcocks, *d* and *e*, are of a conical form; iron gratings are placed within over the orifices of the pipes, and a bed of pebbles is made to fill up the conical portion, over which a cloth of a thick spongy felt is placed—permeable to water, but not to the solid particles of the slip—and firmly secured to the edges of the filter; upon this another cloth of hemp receives the slip. Upon depressing the rod, *m*, which works through the two air valves, *nn*, a direct communication is opened above and below between the reservoir and one of the vacuum vessels, and the atmospheric pressure not being counterbalanced below, exerts its whole action upon the surface of the slip, forcing the water through the filtering cloth into the vacuum. In the course of forty or forty-five minutes a layer of slip of six inches deep, containing rather more than fifty per cent. of water, is reduced to a thickness of two and a quarter inches, and converted into a paste of remarkable plasticity, containing only one-fifth of water. In whatever manner this drying of the paste is effected, it is always obtained of equal consistency, the paste from the sacks or pressing apparatus being firmer on the outside than in the interior. This defect is obviated by a process called *slapping*, the clay, generally preserved in the form of lumps or balls, being forcibly thrown repeatedly against a hard stone or slab of gypsum, rendering it perfectly homogeneous throughout. Sometimes treading under foot, or laceration between metallic plates with a stamper, is substituted for the slapping process.

The felspar and lime in the paste, not being plastic ingredients, and always amounting to one-fourth or more of the whole, considerably interfere with its

plasticity, rendering it very much below that of pure clay. The forming and moulding process is consequently one of great expense and difficulty, so much so, that while a workman employed with assistants in preparing plates from the more plastic earthenware, can produce six hundred in ten working hours, not more than sixty or eighty plates of porcelain can be moulded in the same time. Every precaution and endeavor is, therefore, used to increase its plasticity—such as mixing it with fragments from the moulding operation, continued treading and kneading, and, what is found to be of greater utility, the storing it away in moist layers, in order to engender a peculiar species of decay. The superior value of clay that has been kept a considerable time is well known, and it is never desirable to work paste that has not been stored away in a moist state at least for a year. During this process of *aging*, a curious phenomenon occurs: a fetid smell of rotten eggs is evolved from the mass or lump, the interior portion becoming of a darker color passing from grey to black. This black color is produced by the highly carbonaceous product of the decomposition of organic matter, which, by a constant absorption of oxygen, reducing the gypsum and other sulphates that may be present to the state of sulphides, gives rise to the production of sulphide of hydrogen on the outer portions; and wherever the air has access to the blackened part, the black matter disappears, the oxygen being converted under these circumstances into carbonic acid. It is more difficult to assign a reason for the greater plasticity of the mass that has passed through this process, though it may be probable that the gas, in struggling to escape, more completely pul-

Fig. 472.

verizes the clay, and reduces the whole into a homogeneous mass. So fully aware are manufacturers of the efficacy of this fermentation, that attempts are sometimes made to induce it by the addition of honey, sirup, *et cetera*, to the mixture.

Forming or Moulding of Porcelain.—Porcelain

bodies being more susceptible of inequality of pressure in the process of turning and moulding than earthenwares, require a corresponding greater amount of care. The goods are formed either upon the *potter's lathe* or *throwing wheel*, in *moulds* or by *casting*. The art of *throwing* by the potter's wheel is the most ancient, as well as, from the skill it requires on the part of the workman, the most interesting. The form in which it is now employed in the porcelain manufacture is shown—Fig. 472.—The disc, *a*, consisting of the head, the axle, and the wheel, is placed in the middle of a table, *Δ Δ*, supported by massive framework, and bound together by cross-bars, *a a*, *b b*. The axle, *c*, is made of iron, one end, *d*, rotating on a piece of quartz cemented to

the floor by plaster of Paris; while the other, passing through the brass ring, *e*, screwed to the table, carries the massive block of gypsum, *f*, upon which the operation of forming or throwing is performed. To the lower portion of the axle a wide heavy horizontal wheel, *F F*, is attached, which, from its great weight, mostly accumulated in the circumference, works as a balance wheel, rendering the motion in the upper part, *f*, uniform and continuous—a matter of essential importance.

The *thrower* or workman engaged in the formation of the plastic clay seats himself upon the stool, *a*—Fig. 473—supporting himself with his feet against the board *b*, so as to obtain a sufficiently stable position to

Fig. 473

enable him to rotate the wheel, *c*, with one foot. The mass of dough, as received from the *slapper*, is cut up into portions by means of a brass wire, each portion being weighed by an assistant called the *baller*, accord-

ing to the size and value of the article. The thrower receives one of these masses, and dashes it down upon the centre of the revolving block of gypsum, *d*. The thrower now presses both hands against the mass,

Fig. 474.

which being kept in constant rotation gradually acquires a round form, *a*—Fig. 474—his hands being maintained in a smooth state by dipping them into a vessel containing a quantity of water and paste held in suspension. If it were not for this precaution the

paste would adhere to the skin, and the smoothness of its surface be destroyed. The next operation consists in rendering the piece as homogeneous as possible, by raising it into the tall conical mass *b*—Fig. 474—for the purpose of squeezing out the air. The workman

then forces both his thumbs downwards into the centre of the mass, producing a cavity, which is enlarged as he removes his thumbs one from the other, *c*—Fig. 474—producing a bell shape. The sides of the half-finished vessel are then closely pressed in a slightly upward direction between hands and thumbs, and being lessened in thickness increase correspondingly in height, *d*—Fig. 474—according to the nature of the required vessel. It is in this manner that all vessels of a circular form in horizontal section, *e*—Fig. 473—are produced.

When the mouth of the piece is too narrow to admit the insertion of the hand, as is often the case with a jug, it is either made in two halves, afterwards cemented together, or shaped out by means of a wet sponge attached to the end of a crooked stick. In order to insure uniformity in the sizes of the piece, a gauge is used, consisting of a small rule, *a*—Fig. 475—sliding up and down a rod, *b*, and fixed to any required height by the marker, *c*, the whole being attached to the stand, *d*.

In this process of forming by the hand upon the lathe, the inequalities of the skin produce serrated spiral lines upon the surface of the ware, destroying its neatness and cleanliness. This circumstance, in conjunction with that of the plasticity of the mass not being sufficient to admit of its being worked by hand to that degree of tenuity required by commerce, renders a further operation necessary to bring it to the proper dimensions and perfection of form—the crude shape only being obtained upon the wheel, as will be further understood by reference to Fig. 473. Here the workman is represented as in the act of throwing, working with his hands and feet at the same time, and having a skin or apron, *f*, by his side to receive the fragments of slip thrown off in the operation, while the other operator, *g*, is engaged in roughly finishing the piece by means of the iron gauge in his hand. All vessels of an oval or angular shape which cannot be formed by turning, receive their shape by pressure in gypsum moulds, upon the inside of which the prominent parts of the piece are sunk, and *vice versa*.

This manipulation requires that the mass to be formed be of sufficient tractability to be easily introduced into the cavities of the mould by kneading, and that, when pressed, it be of sufficient tenacity as not to bend or yield upon removal. It must, therefore, acquire consistency, and dry in the mould—a condition which renders it absolutely necessary that the moulds be constructed of substances of a porous nature, otherwise the pieces would adhere and lose their shape upon removal. The moulds are, therefore, generally formed of gypsum—plaster of Paris—and sometimes of burned clay, and are of every variety of size and pattern, a complete set of patterns being required for every new design, and for every size of the same pattern. Moulds for plates, dishes, and other shallow articles, consist of only one piece, while for jugs, vases, and more elaborate forms, several pieces or moulds are employed.

The mode of making the moulds for plates and dishes, and the subsequent operation of moulding, are as follows:—Upon a model, *a*—Fig. 476—composed of either metal or gypsum, and turned in relief to

Fig. 475.

Fig. 476.

Fig. 477.

Fig. 478.

correspond with the exact contour of the inner surface of the plate or dish to be formed a hollow gypsum cast, *b*, is taken. This serves as the matrix, from which, when saturated with oil, innumerable other moulds, *c*, may be taken for use. As gypsum expands in setting about 0.01 of its linear

Fig. 479.

dimension, the original matrix must be made so much smaller. The mould being attached to the revolving

table, *a*—Fig. 477—receives upon its surface the sheet of thin dough, prepared as follows:—The assistant hav-

ing, by means of a wire, separated a piece of dough from the mass, hands it to the thrower, who places it upon the head of the throwing machine, *a*—Fig. 478—over which a piece of wet leather, *b b*, has been previously stretched, after the fashion of a drum, by means of the ring, *c*, the gypsum slab, *d*, fitting on to the socket, *e*. By the revolution of the head, the lump of paste is spread over the surface, and converted into the plate, *f*, which is brought to a uniform thickness by a gauge. It is now removed by means of the leather to the plaster mould, *c*, fixed upon another wheel, and pressed on to it during rotation by a sponge dipped and moistened in *slip*. In this manner the interior form is given to the plate, the outer surface, *e*, being finished off by the profile, *a*—Fig. 479—pressed upon it during its revolution. This profile, formed of a thin piece of brass plate, is mounted upon a carrier or slide, *b*, the adjustment being arranged by screws, *c c*, passing through the holes, *d d*. The excess of paste that extends beyond the proper outline is turned off, and the plate left in a finished state. The maker's name being impressed, the mould, with the plate upon it, is then conveyed to the drying chamber and placed upon a shelf, where it remains till sufficiently hardened to bear removal. In the meantime the operation at the lathe proceeds with other moulds.

In the process of drying, the gradual evaporation of the water contained in the paste brings the solid particles closer together in proportion as the moisture disappears. A consequent shrinking or diminution of volume takes place in the mass, the proper proportions remaining unchanged when the shrinking and desiccation have been uniform throughout; but, if this be not properly effected, distortion is the result. For this reason the pieces after they leave the lathe cannot be dried in a stove or current of air, or even by exposing them to the sun; for by such means they are desiccated only upon the outside, while the interior still contains a sufficient quantity of moisture to cause them to split with a kind of explosion in the furnace. They are, therefore, carefully stowed away in the shade upon wooden shelves, until no more moisture can be evaporated from them.

Fig. 480.

Sometimes the inner surface only of the ware is formed by the hand, the paste, *a*—Fig. 480—being pressed against the mould, *b c*, during its rotation, forming the vessel, *d*; the sheets of paste considerably thicker

than the sides of the future vessel being prepared by rolling on a moistened gypsum slab, *a*, under a wooden roller, *b*—Fig. 481. When, from the elegance or complication of form, the admission of the hand into the mould is impossible, it has been stated that double

Fig. 481.

moulds are used. These are shown in Fig. 482, the paste, *a*, being first laid upon the solid form, *A*, and turned over into the mould, *b*, the interior mould being

Fig. 482

furnished with cavities, *d d*, for more easy removal. Fig. 483 represents the operation of moulding and finishing the additional pieces, such as the spout, handle, *et cetera*. The thin sheet of paste, *a*, prepared by rolling at *A*, is carried to the moulder, *B*, who, pressing with a damp sponge, makes the paste adhere to the mould, *b*. The latter is placed upon a circular plaster frame, *c*, mounted upon the iron axis, *d*, which can be revolved at pleasure by the hand of the workman. A further stage is shown at *c*, while the workman, *D*, is moulding a handle, *e*, for the sugar basin, *f*, removing the roughness, and filling up all cavities left by the moulding.

The porcelain paste, from the nature of its ingredients, is exceedingly susceptible to injuries from the least inequality of pressure in the moulding, injuries which are only made apparent at a period of the manufacture when it is too late to rectify them. The principal cause of these is the difference in shrinking during the drying and firing of the parts which have been subjected to different degrees of pressure. These defects are not so apparent when slight pressure only is applied, and may be easily avoided in the ordinary process of moulding; but when the pressure is increased and applied more unequally, they become so marked and unsightly as to render the article useless. Moulding presses are, therefore, only used for objects of small dimensions, in which perceptible differences in the consistency of the mass cannot occur; for larger vessels they are almost

entirely discarded in the manufacture of porcelain. Even when the greatest care is taken in manufacturing

the plate upon the mould, faults will occur; the bottom of the piece, instead of presenting an even surface,

Fig. 483.

will often fall away, as represented in Fig. 484, at *d*—a defect very fatal to the beauty of the subsequent processes of decorating and gilding—and the diameter and thickness will be variable at different places. Some

Fig. 484.

of these faults may be traced to the inequality of dampness in the surface of the mould, but generally to the unequal consistency of the mass used. To prevent loss also in the drying process, it is very necessary that all air be removed from the surface of the paste, as the presence of any particles of air, however minute, is sufficient to cause the splitting of the piece. If the plaster composing the mould also be not perfectly homogeneous and equally dense in all its parts, the absorption of moisture will be very irregular, causing a corresponding inequality in the separation of the paste from its surface.

When a dry gypsum mould is dipped in water, a certain absorption by capillary attraction takes place, the pores becoming filled; and should it happen that the water in which it was dipped held in suspension any particle of clay or other muddy substance, a kind of filtration occurs, the clay being left upon the surface of the gypsum, where it conglomerates and sets, the thickness of this deposit depending upon the duration of the operation, the massiveness and absorbing powers of the mould, the nature of the substance, and dilution of the paste. A very plastic material and pure clay soon form an impenetrable crust, which prevents further increase in thickness; but the flux in the porcelain paste, preventing the particles from

coming into too close proximity, admits of absorption taking place through the deposits already formed. For the purposes of casting, the slip is stirred up into a thick but perfectly liquid state, and passed through sieves, that all granular particles and bubbles of air may be separated, the number and nature of the moulds depending upon the form and elaboration of the article required. Thus in the case of the jug—Fig. 484A

Fig. 484A.

—the foot, *d*, body, *c*, neck, *b*, and handle, *a*, are each cast in a separate mould, the prominence of the parts requiring these distinct operations. The neck, *b*, is moulded in an inverted position, *a a* being the sides of the mould, *c* the aperture through which the slip is introduced, and *e* that through which it is withdrawn.

The same manipulation is applied to the moulds for the other portions, which, being closed below, are completely filled with the semifluid slip, and allowed to remain for two or three minutes before the water is rapidly drawn off, leaving a residuum of from one to two lines in thickness round the sides of the mould. The casting for the body, *c*, of the jug proceeds in exactly the same manner, but the mould is emptied by inversion. The various pieces having been removed from the moulds, and cleaned from superfluous paste, are put together and joined while in a moist state, the connection being so perfect that no indication of it is perceptible. The handle is put on afterwards—see *Earthenware*.

In the moulding of a teapot, five moulds are again required—two for the formation of the exterior form, and three for the interior manipulation, the parts being afterwards united together in such a manner as to produce the interior development of the spout and double casing of the sides necessary for strength and utility. The pieces must remain in the moulds, however, for a considerable time before they acquire proper consistency; the operation of moulding, therefore, requires much time and numerous moulds. Many articles likewise, even without appendages, such as a vase with a narrow neck, cannot be cast in one circular piece, which could not be extracted from the mould even by inversion. Such articles can only be made by casting in two halves, to be afterwards joined together.

In casting, the pieces are never perfect or free from blemish, as they leave the moulder, but require often tedious finishing processes, such as *turning*, *retouching*, *ornamenting*, and the adaptation of the separately moulded pieces to each other.

Turning.—Many articles are made much thicker upon the throwing-wheel than they appear when finished, the superabundant mass being turned off in a lathe to give the requisite beauty and uniformity of *contour*. This turning is precisely similar to that practised in the earthenware manufacture—which see—the clay being in such a state as to throw off a connected shaving without either crumbling or adhering to the tool. In this operation the piece is fastened to the gypsum slab of the throwing-lathe, by moistening the bottom, or fixed on to the lathe in a horizontal position by means of an ordinary chuck, as the case may require, ordinary sharp flat knives being used as tools in place of the chisel. One of the chief points in the finishing operation consists in the removal of the edges or seams caused by the penetration of the slip into the joints of the moulds. It is necessary that the seams should be carefully pared away with a knife, as, if removed by pressure only, they appear again after burning.

The casual cracks and indentations have at this stage of the manufacture to be carefully filled up, and all engraved or carved work which requires cutting away with the knife, to be performed. Frequently an ornamental appearance is imparted to the ware in this state by impression upon its surface with the *roulette* or stamp, in the use of which turpentine is applied to prevent adhesion to the paste, the fatty oils

not producing the necessary effect. It has already been stated that such parts as handles, feet, *et cetera*, are formed or moulded separately, and fixed upon the porcelain before firing, but smooth handles of uniform dimensions are often formed by pressure through an aperture of corresponding shape and diameter—see *Earthenware*—while those of more elaborate pretensions are produced by moulding in gypsum moulds. The union of all such parts with the body is effected by sticking them together under very gentle pressure, the two opposing surfaces having been previously roughened and covered with slip. All changes which affect unequally the mass of the vessel and the ornamental parts tend to cause cracks during the drying, and to separate the latter. It is therefore essential that the body and the ornamentation of the vessel be equally dry, and that the surfaces be prepared either by turning or casting in the same manner; also, that all excess of slip, from the increase of moisture it contains, be avoided. The same precautions apply to the joining together of pieces moulded in separate forms, the surfaces of which should be retouched with a sponge or wet cloth.

Firing.—In the operation of firing the true porcelain with the glaze—see *Glaze*—is rendered dense, vitreous, sonorous, and translucent, the glaze being of that nature that it melts at the temperature necessary for the perfect firing of the mass. The waste heat from this process is employed to produce the ware in the state of *biscuit*, or, in other words, for the firing previous to glazing.

On account of the chemical composition of the substance and the refractory nature of the glaze, the greatest possible amount of artificial heat that can be produced is required. This intense heat is the more necessary, as from the white color of the material, the transparency of the glaze, and its softness at high temperatures, it cannot be exposed to the direct action of the flame. Porcelain, like many other kinds of clay wares, is always, therefore, inclosed during firing within clay vessels or *seggars*—see *Earthenware*. This high temperature of the furnace must, for the successful firing of the pieces, be maintained as steady and uniform as possible, otherwise various misfortunes, such as splitting, bending, and fusing, will ensue. To effect this, with the large quantity of materials and the considerable number of seggars fired at once, requires a peculiar arrangement of furnace; as the porcelain goods cannot be brought into direct contact with the fuel, without impeding the draught, and causing a want of regularity in the distribution of the heat throughout the mass. All pottery requires, therefore, to be baked in a reverberatory furnace, in which the fire being kindled upon a separate grate does not come into contact with it. In short, potters' kilns are all reverberatory furnaces, which possess the advantage of surrounding the seggars more completely with flame, and of imparting a more uniform heat than would be practicable were they placed in direct communication with the fuel.

Furnaces.—The porcelain furnace is very similar to the glass furnace, with the exception that the source of heat is dispersed over several grates situated at the

circumference of the base instead of being united into one central fire. It consists, therefore, of a round chamber, on the floor of which the seggars containing the ware are arranged and piled in columns or *bungs*, the flames ascending from a number of wide flues below and around, in connection with the same number of fire-places, so as to circulate between the columns of seggars, filling the whole space, and escaping through different apertures at the top of the chamber into a second room, where they are again employed for heating the *biscuit-ware*. The details of one of these porcelain kilns are shown in Fig. 484B, one-half of which is

in section and the other in elevation, the horizontal section—Fig. 484C—being partly on a line through the fire-bars, and partly through the upper chambers, showing the vent-holes for the circulation of the flame.

The kiln or oven is surrounded by four or five separate fire-grates, A, A, A, A, which first heat the space, L, where the *porcelain* is burnt; then the second chamber, L, where the *biscuit* is baked; and thirdly, the space, G, used either for a similar purpose, or for the firing of the *seggars*—the flames finally escaping through the chimney, c. In the construction of the hearth of the

Fig. 484B.

porcelain kiln, the draught is forced to take a direction contrary to that usual in other furnaces. The space, c, being filled with hot charcoal, wood in small billets is introduced through the aperture, b' b', so as completely to fill the space, f. The draught, therefore, in the first instance, assumes a downward direction through b, as indicated by the arrow, and reaching the burning wood between f and c, induces a long flame, which

escapes through the opening, p, into the chamber, L, where combustion is completed. The difference between this arrangement and that of an ordinary fire grate is this, that while in the one case the glowing fuel is brought into direct contact with the external air, and the flame has to pass through the freshly added fuel, in the porcelain furnace the combustion is kept up by air already heated by its passage through the upper

layers of fuel, and the combustion rendered more complete. The hearth of the furnace is composed of a bad conductor of heat, such as bricks; and the velocity of the draught being reduced on entering the wide cham-

ber, *L*, greater time is allowed for the perfect combustion of the volatile products from the fuel. The small aperture, *o*, employed for the purpose of stirring the fire, is closed with a clay stopper, while the opening, *b*, at the foot of the hearth serves for the removal of ashes, *et cetera*. The regulation of the draught is effected by the lid, *b' b'*, the aperture or flue from which, before entering the furnace, is divided by tongues, *g g*, into the channels, *p p p*, for the better dispersion of the flame. *D* and *E* are doors for the insertion and withdrawal of the goods. In the arched covering of the space, *L*, twenty-five apertures or flues, *t, t*, are left to conduct and spread the flame as it enters the second chamber, *L*, the effect of a single opening in the centre being to draw the flame to one spot. Similar openings, *t, t*, but of half the number, conduct the flame from *L* into the upper chamber, *c*.

For the purpose of examining the progress of the firing, and for the introduction of small samples or *watches* into the seggar nearest the hole, small openings, *v*, are made in the walls of the chamber, *L*. These *watches* consist simply of pieces of biscuit covered with glaze, by the appearance of which, and the degree of fusion they undergo, an indication is given as to the state of the porcelain vessels. In order to prevent the access of air into the furnace through the opening, *v*, a tube—Fig. 484D

—is introduced from the outside, supplied with an iron damper, *z*, sliding in the frame, *h*, and closed in front by a plate of glass. These furnaces, averaging about twenty feet in diameter, and forty feet in height, are constructed internally of fire-stone, surrounded by an exterior casing of ordinary brick, the whole being bound together by iron stays or bands, *m, r, u, z*. To prevent their cracking or giving way by the great expansion caused by the heat, elastic hooks connect these girders together, and enable them to meet the strain. An improved modification of this furnace has recently been patented in France by M. VITAL ROUX of Noirlac, with a view to the employment of coal as fuel in the manufacture of true porcelain, without the necessity of reconstructing the entire kiln. It consists of the insertion of a grate at *g*—Fig. 484E—by which the air is allowed access to the fuel from below through the channel, *i*, as well as from above through *g*; the number of fire-places is increased to eight or ten, according to the dimensions of the kiln. It has been found to produce ware much more evenly fired throughout the kiln, while the lining of the furnace and the seggars are less attacked. In consequence also of the draught being greatly increased, and the ash of the coal containing only a very small proportion of alkali compared with that of wood, the clay does not

vitrify and destroy to such an extent. The saving in the expense by employing coal instead of wood, is calculated to average from sixteen pounds to sixteen pounds

Fig. 484C.

ten shillings for each firing. A vertical section of a porcelain kiln is represented in Fig. 484F; the interior arrangement and piling of the seggars, one upon another, being shown, together with the ordinary contents, such as plates, *a a*, vases and jugs, *b b b*, tubes, *c*, and a porcelain slab at *d*. The partitions which divide the

Fig. 484D.

Fig. 484E: A vertical cross-section of a porcelain kiln. It shows a large arched interior space. At the base, there is a grate 'g' and a channel 'i' for air flow. The interior is filled with various items: plates 'a a', vases and jugs 'b b b', tubes 'c', and a porcelain slab 'd'. The structure is supported by a brick base and has a thick exterior casing.

Fig. 484E.

Fig. 484F: A vertical section of a porcelain kiln showing the interior arrangement and piling of seggars (one upon another) along with ordinary contents like plates, vases, jugs, tubes, and a porcelain slab. The diagram illustrates the internal structure and the placement of various items within the kiln.

flame on its entrance to the furnace are shown at *ee*, while *fff* are plates of refractory clay, called fire-guards, which prevent the flames and ashes from coming

into contact with the seggars. *ggg* are props for supporting the seggars. In Germany the furnaces are very similar in construction, but the apertures from one

Fig. 484F.

chamber into the other are only seven in number. They are wider, and furnished with short chimneys, which project it on the upper chamber, L.

The idea of supplying fires to both floors of the furnace, and obtaining the greatest amount of heat, in the hope that the expenditure of fuel in the upper floor would be proportionably less according to the amount of heat derived from the lower one, has been tried at Sèvres, but the results have by no means realized the expectations of the inventors.

Kilns for true porcelain are much more durable than glass furnaces, being free from the destructive action of the volatile alkalis; on an average they last three hundred firings, while in some places they have endured a much longer period. A dry foundation, exerting as little cooling influence as possible, is an important point in their construction.

Fuel.—In regard to choice of fuel, the porcelain manufacture is much more circumscribed than any other industry. It is only those kinds of fuels which burn with a flame that can be employed, and their comparative value depends upon the length and vigor of flame they afford in combustion. Another important requisite in connection with the fuel is, that it should discharge as little dust and ash into the kiln as possible, as this, penetrating between the joints of the seggars, produces black spots upon the surface of the ware. Amongst the varieties of wood in use, preference is given to the light kinds, as poplar, pine-

wood, *et cetera*, cleft into small billets; the effect of which is, that more wood is consumed at once, and a larger flame produced. The wood is not artificially dried, and retains from six to ten per. cent. of moisture. The use of peat has not been found satisfactory as regards the quality of the wares.

Firing.—After the chambers of the furnace have been charged with seggars, the apertures are all closed, and the process of *firing* commences. In this process there are two distinct stages—the first intended only to expel the moisture which may still remain in the vessels, and gradually raise them to a red heat, while the second completes the baking of the porcelain. At the commencement the firemen keep the upper aperture of the fire-hearth closed, the plate *b'*—Fig. 484B—being only removed for an instant as fresh fuel is thrown into the fire; the draught, therefore, enters through the ash-pit, *b*, in the same direction as in an ordinary furnace, producing a smoky, carbonized flame. In this operation the wood is thrown in irregularly in thick billets, crossing each other in various directions, until the furnace is found by examination through the test-holes, *v*, to have attained a cherry-red heat. This being the case, the space, *f*, is filled up to *b'*, with logs of from one to one and a half inches thick, laid parallel, and which are of the same length as the breadth of the hearth; the lower opening, *b*, is then closed. The draught being now reversed, the heat increases, and the smoke entirely disappears,

while the process of *baking* commences, and nothing visible escapes from the chimney but a stream of hot transparent gases. During this process, from the intense draught, the fuel is entirely consumed, all ash being carried away; as after the firing, ash which, from the quantity of wood consumed, should amount to over two hundredweight, does not yield, ash and charcoal together, a cubic foot. Any irregularity in the firing is immediately perceptible, the heat of the furnace diminishing directly on that side where the firing is badly attended to. When any one of the fires is out of order, the red-hot charcoal not being properly consumed, stops the progress of the flames, and causes them to beat back, a fault only remedied by the removal of the charcoal as rapidly as possible. A similar effect in the irregularity of the combustion of the fuel is caused by repairs upon the furnace. At Sèvres, for instance, when one half of a furnace had been newly constructed, it was found that the ware situated upon that side was thoroughly baked two or three hours before the other contents were fired, an old furnace always working more slowly than a new one, and requiring from five to six hours longer to complete the baking. In general the first process of firing occupies half as long as the baking, lasting from seven to eight hours, and the firing from eleven to thirteen. In some instances the two processes, as at Berlin, are nearly the same, the one taking from twelve to fifteen hours, and the firing from seventeen to eighteen. At Sèvres, again, the first is the longer process, occupying from fifteen to eighteen hours, while the baking only takes from ten to twelve hours. The temperature upon the upper floor of the furnace ranges from 30° to 60° of Wedgwood's pyrometer, while that of the lower chamber is from 130° to 160° Wedgwood, the heat of the base of the furnace being some 40° less. The *pyrometer* introduced by WEDGWOOD as a measure of high temperatures can only be employed as affording a useful approximation, and not the accuracy required for scientific purposes; the contraction of the clay under the action of intense heat being the principle upon which its measurements are made. This contraction is variable, even when the same kind of clays are placed side by side in the furnace, and a good pyrometer that shall indicate exactly intense degrees of heat is still a desideratum. As nearly as can be ascertained, the relative value of one degree of heat on the pyrometer, compared with that of the mercurial thermometer, is about 72° of Celsius, or 130° Fahrenheit, the zero of Wedgwood being about 580° Celsius, or 1076° Fahr., so that the greatest degree of heat in the baking will range from 19832° Fahr. to 21632° Fahr.

At Sèvres the average amount of fuel consumed as a mean over twelve operations in a double furnace, with two great fires, was found at first to be seventy-three cubic metres, which gradually diminished at the end of twelve months to fifty-two cubic metres; the mean quantity of porcelain baked during the period was seven hundred and eighty-four kilogrammes, and the seggars required for incasing it fourteen thousand kilogrammes, being in mass eighteen times that of the porcelain. In a kiln—represented at

Fig. 484B—the cost of firing one kilogramme of porcelain may be taken as two francs—or one shilling and eightpence; while the cost of a cubic foot of space in the furnace will be one franc one centime—about tenpence. In Vienna, for every firing about seven klafters of wood are used, equal to sixteen and a half stacks, each of one hundred cubic feet, Hessian; in Berlin ten stacks, about seven hundred cubic feet, same measurement.

In consequence of the glaze of porcelain being a true glass, and entering into the mass, the process of annealing requires to be carried out; that is, the material must be cooled slowly in order to prevent it becoming brittle. This is rendered necessary from the circumstance that the particles of the glass, while in a fluid state, have a tendency to arrange themselves in a regular manner, and form crystals; whereas, by the process of cooling suddenly, they are forced to remain in the relative position towards each other which they assumed during the working; and this constrained state is greatest at the surface, where the cooling and contraction have been most rapid, the interior of the mass being less affected. These outer layers are consequently in a state of tension with reference to those in the interior, and a want of uniformity in the results, inducing a tendency to destroy the cohesion of the whole, which the slightest impulse from without will be sufficient to overcome. It is not necessary to employ any separate kiln for this annealing process, the kiln, with its contents, being simply bricked up after firing until it has become sufficiently cool to be emptied. A period of from five to eight days is allowed for the gradual reduction of temperature. In general the kiln is opened the evening before the porcelain is removed, the annealing process being thereby rendered more complete.

Seggars.—The composition of which the *seggars* are composed at Sèvres consists of forty parts plastic clay, sometimes decanted, and sixty parts of ground fragments of old seggars, or an equal quantity of a mixture, containing equal proportions of fragments and crushed quartz sand. At Meissen sixty parts of clay are used to forty parts cement; at Berlin 66·7 clay to 33·3 cement. At Sèvres it has been ascertained that the average duration of the seggars is fifteen firings or more; at Vienna from four to five; and at Berlin only from two to three; in which latter case, the loss occasioned by the seggars becoming useless amounts to nearly thirty dollars, or about four pounds ten shillings at each firing. At Meissen twenty per cent. of the seggars are lost at each firing. These differences result entirely from the local inequalities of the plastic clay, even when obtained from the same deposit, the loss becoming heavier, inasmuch as bad seggars cannot be piled so high in the kiln as good ones. The interior surfaces of the seggars are sometimes glazed, as they have been found to suck up the glaze from the porcelain, exerting a chemical attraction for it by facilitating the volatilization of the potassa, and absorbing it upon their inner surface. It is also of great importance to pay attention to the shrinking of the clay wares upon introducing them into the seggars, as when any obstruction prevents them from shrinking uniformly in their soft-

ened state they become warped and twisted, while the unevenness in the bottom of the seggars renders it necessary often to support the pieces by other means. The form, also, which is given to the seggars is a point of the utmost importance, since the quantity of goods that can be placed in the furnace at the same time depends upon it; and the amount of cost in the firing of each piece is lessened in proportion to the number of seggars that can be properly packed into the

Fig. 484g.

furnace for the same firing. All seggars are, therefore, made in the form of shallow cylinders, except when the particular form of the piece requires it otherwise, and the bottom being flat, each seggar forms the lid of the one placed underneath. Several vessels are placed in one seggar—Fig. 484g—and in order to insure the wares standing upon a perfectly smooth and even surface, small ground plates, *b b b*, are introduced, consisting of the same material as the seggars, and which can be easily taken away and repaired as required. In order to prevent the ware adhering to the plate, the glaze is removed from those parts of the piece

Fig. 484h.

that come into contact with it, and as even those parts which are free from glaze are liable to soften and adhere, sand is interposed to prevent such occurring. Seggars which are intended to support hollow wares,

VOL. II.

such as plates, pans, saucers, *et cetera*, are constructed with a curved bottom, which, projecting downwards into the hollow of the vessel situated in the seggar beneath, economizes space; in this way from twenty-nine to thirty plates may be packed into a space which would otherwise have only contained twenty. The bottoms of the seggars are, with this view, constructed in a separate piece, *b b*—Figs. 484g, 484i—which has the advantage of enabling the seggar better to withstand the action of heat without fracture.

A form of seggar was introduced at Sèvres in the year 1839, by REGNIER, which has the advantage of economizing still more the space occupied in the disposition of the pieces, as well as of protecting them from the minute particles of ash carried during the firing through the kiln, and which, as already mentioned, affect the purity of the ware. The principle upon which this seggar is constructed is shown at Fig. 484h—the plate or ware being inclosed in a double casing, an inner and an outer one; and this arrangement requires the two parts to be slightly different in composition. The exterior casing is composed of forty parts of ordinary plastic clay decanted, and sixty parts cement; while the mixture for the interior seggar contains twenty parts ordinary plastic clay decanted, twenty parts of the best plastic clay, thirty parts cement, and thirty parts crushed quartz sand. The outer seggar, *t t*, con-

Fig. 484i.

sists only of a hollow ring with a projecting ledge upon the interior of the upper edge to support the plates in their respective seggars, *i i* and *s s s*, which together form one closed vessel, the rim of the lower one, *i*, forming the sides. One plate being inclosed in each of these chambers, a second one is supported between each pair of seggars, the lowest chamber of the series being of necessity formed as at *c' c'*. In this manner from fifty-one to fifty-two plates can be fired in a space that was occupied by from twenty-nine to thirty, with the construction shown at *c c*, and by only twenty when the seggars had flat bottoms, as at *A A*. This economy of space, amounting to seventy-five per cent. in the height, is reduced to forty-five or even twenty-five per cent. with wares of a less flat outline; the cost of firing one hundred plates upon the new method being two pounds seventeen shillings against four pounds eight shillings as formerly, or fully thirty-six per cent. less. Some

5 K

wares, on account of their undulated and varied form are apt to become distorted in the firing, and, therefore, require supports to keep them straight. Thus the two mugs, *e e*—Fig. 491—placed one above the other, are separated by the ring, *c*, round which a groove is run at the top and bottom to receive the edge of each cup. The cup, *g*, is furnished with a lid, *o*, which does not belong to it, but is only employed for the purpose of retaining the edge in a perfectly true and circular form. The rim, *v*, of this lid is conical to enable it to rise in proportion as shrinkage takes place in the vessel. To enable vessels of larger size having handles to be fired, the seggar, *c c*—Fig. 484k—is formed with a prominent part for the support of the handle.

Fig. 484k.

When all the seggars are properly arranged and safely piled in the furnace, the joints being secured to protect the glaze from particles of falling dust, the firing is proceeded with, and here great care is necessary to insure that all the articles in the kiln receive the proper degree of heat—too much heat causing a partial fusion, and too little leaving them incompletely burnt. Although the mode of building the kilns insures a tolerably uniform distribution of heat throughout the mass, all parts are not equally hot, these immediately in front of the stoke-holes being much more intensely heated than such as are situated between them. At different heights also a different temperature is attained, the heat being less intense immediately at the bottom, while the greatest intensity is acquired about the middle, diminishing again as it proceeds towards the top.

The piling of the seggars in columns or bungs in the furnace requires great experience and caution on account of the very narrow base they rest upon compared with their height. By the contraction or expansion in the separate pieces an alteration in the centre of gravity will sometimes occur, affecting the stability of the structure so much as often to bring down the entire column, and even those in proximity to it, reducing the whole to a mass of fragments. Frequently a break down of this kind arises from the fracture of a lower seggar unequal to support the weight of the superincumbent mass. The lower seggars require, therefore, to be made stronger and the height of the column to be reduced as at Berlin, in proportion as the quality of the seggars deteriorates by repeated firing. Care must also be taken to place the more massive wares in the centre of the furnace where the heat is greatest, and the thinner and more easily

distorted articles in less heated parts. In order to protect the seggars immediately in front of the furnaces from the too intense heat, hollow semicylindrical screens of clay, *ff*, are employed—Fig. 499. The tendency of the columns of seggars to lean and tumble over is counteracted by the insertion of clay between each pair, and the stability of the mass is further insured by the support of broken pieces of seggars, a space of from two to four inches being left between the columns for the free circulation of the flame. In order to prevent the lowest seggars of the tiers from uniting with the floor of the furnace by fusion with the ash mechanically carried with the flame into the furnace, a layer of sand is interposed. Those seggars intended to receive the tests, and which have corresponding apertures in them are placed opposite to the small watch-holes of the furnace.

After firing the wares are removed from the seggars, and the sand which may have attached itself to the bottom, where they rested on the seggars, is ground off by a piece of sandstone or some soft artificial substance, used as a kind of file; while those articles which have been spoilt by bending are assorted and placed aside. This warpage of the ware is sometimes of considerable amount; at Vienna, for example, only three plates out of four come perfect and sound from the firing. Even in the so-called perfect ware there is always something to correct—such as dark points caused by the adherence of minute grains or splinters that have separated from the seggars; or a deficiency of glaze upon the parts which have been in contact with the supports, causing them to appear dull and rough, with a total absence of lustre, and which can never be kept so clean as the glazed portions. When this occurs at the bottom, it is of much less consequence than if on the edges. Such parts are re-glazed afterwards by means of a brush, and exposed a second time to the furnace—an operation of equal risk and expense with the first firing. Sometimes an easily fusible lead glaze is burnt upon these parts in a muffle, but this never acquires the degree of hardness which characterizes true porcelain. For these reasons the inequalities are now commonly removed by a grinding wheel, and the edges and such portions polished finally with tin-ashes, a plan which admits of greater scope in placing the vessels in the furnace and omitting to glaze them in different parts, and one also by which the best ground for gilding is obtained.

The qualities which distinguish porcelain from other wares are its pure milk-white color and entire absence of porosity, together with the very intimate union of the glaze with the mass, and its indestructibility when exposed to sudden changes of temperature. This entirely depends upon the liquefaction of the glaze occurring simultaneously with the complete firing of the ware, and both being nearly equally expansible by heat; the similarity of constitution in the flux and the glaze exerts the greatest influence in this last particular. The *shrinking* which porcelain undergoes, in common with all other wares, is the most important change that takes place, and one which varies with the least alteration in the quality of the body; but which may always be calculated from its remaining constant in mixtures

constituting the same body; the lineal contraction, or shortening in one direction, being on an average thirteen per cent., but sometimes falling as low as seven, and at others extending to seventeen per cent., while the contraction in volume amounts to thirty-nine per cent. on an average. A fourth of this contraction occurs during the first process of firing, and the remaining three-fourths during the subsequent baking of the mass. It may be accounted for in two ways—the evolution of all moisture, and the incipient fusion of the mass during firing. The amount of contraction will vary, therefore, according to the mode in which the mass was formed, the pressure it was subjected to, and the moisture it contains; the shrinkage being least in pressed objects, increasing in those formed in moulds, still greater when the formation of the ware has been on the

throwing wheel, and greatest of all in such as have been cast in moulds. These facts explain why those portions of the ware which have been subjected to less pressure, project after firing beyond such as have been more forcibly pressed. The density of porcelain, and consequently its specific gravity, increases as its volume is diminished; the specific gravity of the dry mass, after the first firing, being 2.305, which after baking is increased to 2.478. This applies to the mass as a whole, and includes the pores. The result is different, however, when its porosity is destroyed, and its specific gravity is taken in the state of fine powder; it is then found to diminish with the increase of temperature to which the mass has been exposed, and the amount of contraction it has undergone—see CLAY. This has been found by experiment as follows, in specimens of—

		Specific gravity.	
		G. Rosa.	Malaguti.
Once heated porcelain,.....	Adhering to the tongue,	2.613	2.619
After three hours' baking,	Adhering to the tongue,	2.589	2.440 half baked.
After four hours' baking,	Adhering to the tongue,	2.566	
After nine hours' baking,	No longer adhesive,	2.452	2.242 thoroughly baked.

It follows from these results that the cubic foot of really solid matter, weighing eighty-two pounds, becomes reduced to seventy pounds; and this is accounted for, first, from the fact that nearly all bodies are rendered specifically lighter by their transition from the crystalline to the melted vitreous state, as is the case with the felspar employed in the manufactory at Berlin, the specific gravity of which is 2.592, but is reduced after fusion to 2.384. The specific gravity of the kaolin is likewise diminished in this manner from 2.633 to 2.562. In the second place, the expansion may also arise from a partial chemical reaction of the

ingredients—a fact very probable from the specific gravity of the mass not corresponding with the mean specific gravity of the component parts. The separate particles of the porcelain become, therefore, permanently expanded during baking, but, at the same time, are brought into closer proximity with each other, and goods that have been once heated are not altered in weight by being thoroughly baked. The contraction of the mass composing the seggars is very much less, and often imperceptible.

The following analyses of different specimens of porcelain may be given:—

Place of Manufacture	Silica.	Alumina	Potassa.	Protoxide of iron.	Magnesia.	Lime.	Analyst.

Paris,	58.0	34.5	3.0	—	—	4.5	Laurent and Malaguti.

THE GLAZE.—At Sèvres the glaze is composed of the pegmatite from St. Yriex, which is felspar, incorporated with a certain proportion of quartz. Although the proportions of these two constituents may vary considerably in small pieces, this ceases to be the case in the enormous mass prepared at the same time at Sèvres, as shown by the following table:—

Component parts of the glaze.	1826.	1839.	1839.	1841.	1842.
	Berthier.	A. Laurent.	Malaguti.	Marignac.	Salvetat.
Silica,	73.0	74.0	73.4	74.6	74.3
Alumina,	16.2	18.6	15.7	16.0	18.3
Potassa,	8.4	6.6	7.4	8.1	6.5
Lime,	—	0.4	1.9	1.2	0.4
Magnesia, ...	—	0.3	0.3	—	0.2
Loss by water,	0.6	—	1.3	—	0.3
Loss,	1.8	0.1	—	0.1	—
	100.0	100.0	100.0	100.0	100.0

The mean of these analyses corresponds with the formula—

In some places, as at Berlin, Nymphenburg, and Meissen, the glaze is composed of kaolin, gypsum, and broken porcelain, equivalent to a gloss containing alumina and lime, with no more potassa than the small quantity contained in the felspar of the kaolin and broken porcelain. In the beauty of the porcelain, everything depends upon the proper fusibility of the glaze, as when too difficult of fusion it does not become fluid enough to form a smooth and even surface, but appears wavy; while, should it be too easily fused, it becomes liquid before the paste is sufficiently baked, and when the latter is still so porous as to suck in the glaze, in consequence of which the ware afterwards presents a rough and dry appearance. As has been before stated, all the ingredients of the glaze require to be

finely pulverized, decanted, and mixed in the same manner as the paste composing the ware. The operation of putting on the glaze can only be accomplished in a rapid and uniform manner by dipping the pieces into a vessel containing the glaze in the form of slip suspended in water; and as, in this operation, the wares, if simply dried, would not only be liable to bend in handling, but would also absorb the water too slowly, they are previously fired to a certain extent, in which state they are called *biscuit*, in order to counteract this tendency—see *Firing*—and after having received this first firing, they absorb, when dipped into the mixture, a certain quantity of water, leaving the suspended glaze attached to the surface. The quantity and thickness of the coating will depend, therefore, very much upon the porosity and massiveness of the vessel immersed, the amount of glaze slip held in suspension, the length of time the vessel is kept in the liquid, and the dryness of the biscuit previous to dipping—circumstances all more or less tending to render the deposit of glaze unequal, and only guarded against by proper care in the preparation of the biscuit, and reduction of the slip to a proper consistency. In general, a very short immersion, varying from twenty to forty seconds, is sufficient; the more rapidly that the operation is performed, the more uniform will be the absorption of the liquid; and to insure this as far as possible, that portion of the ware which was first dipped into the glaze is always first removed. After the dipping process has taken place, the part of the piece held by the workman is coated with glaze by the aid of a brush, and the glaze is removed from those parts of the vessel which, coming in contact with the seegar in the operation of firing, might cause adherence by its fusion.

The process of dipping the *biscuit* wares into the glaze tub is shown at Fig. 484L. The operator, A, holding the plate with the right hand by the rim, plunges it into the liquid, his left hand receiving it at the opposite side upon emersion; the workman, B, dips it again vertically, holding it so as to allow the excess of glaze to run off; the assistant, C, removes the glaze from the bottom of the plate to prevent it adhering to the support on which it is placed for the purpose of firing. As the pieces are taken out of the trough they are placed upon the shelf, *g*, the sieve, *t*, being employed to separate the froth or other impurities floating upon the surface of the glaze. The *blunger*, *p*, is for the purpose of agitating the glaze and maintaining it at a proper degree of consistency; *b* is a vessel containing vinegar, used for mixing amongst the glaze from time to time; and *c* is a small cup containing glaze and a brush for retouching defective portions wherever the glaze is uneven or coated too thinly. It is obvious, that if

during the operation of glazing, the mixture is allowed to settle down, the coating of glaze in the dipping process will be unequal. The liquid is, therefore, stirred from time to time, and some substances mixed with it

Fig. 484L.

to prevent the slip from being deposited. Vinegar exerts a most remarkable effect in this particular; for instance, glaze in water at a temperature of 68° requires only four hours and twenty minutes to separate; in water, at a temperature of 140°, three hours; while in water containing three-seventh parts of vinegar it requires six hours; and in water with one twenty-second part of gum-arabic eight hours, under similar circumstances. When a thinner coating of glaze is required upon any particular part of the ware, that part is moistened previous to immersion, while places desired to be entirely free from glaze are coated with a mixture of wax and tallow. When necessary, a portion of the glaze may be removed by the application of the brush, or the whole by scraping with a knife.

Decoration of Porcelain—see also *Earthenware*. From the nature of the surface of porcelain being that of a true glass, it is the best adapted of all clay wares for the purposes of ornamentation with pigments and metallic lustres; the art being analogous in fact to glass-painting, with the difference that the coloring is solely adapted for reflection and not for effect by transmitted light. All the pigments, therefore, are colored glasses, which acquire their lustre and adhesion to the mass by fusion, and consist of a *flux*, with the addition of a *coloring* ingredient, generally a metallic oxide; such tints as will not withstand the agency of heat being, of course, excluded. Some of the metallic combinations in use for producing the various hues are given below:—

1. Yellow, Oxide of titanium.
2. Yellow, { Chromate of lead and chromate of baryta.
3. Yellow—different tints, Oxide of antimony.
4. Orange-yellow, black, Oxide of uranium.
5. Yellow tints—red, brown, violet, grey, sepia, black, } Oxide of iron.

6. *Violet, brown, black,*.....Oxide of manganese.
7. *Blue, grey, black,*.....Oxide of cobalt.
8. *Brown,*.....Protochromate of iron.
9. *Beautiful black,*.....Sesquioxide of iridium.
10. *As an addition to carmine*
 and purple,..... } Chloride of silver.
11. *Purple,*.....Purple of cassius.
12. *Red,*.....Suboxide of copper.
13. *Green,*.....Oxide of copper.
14. *Green,*.....Oxide of chromium.

Transparent and opaque colors or enamels are used with equal effect upon a white and almost opaque ground, such as porcelain. Transparent colors are rendered *opaque* by the addition of oxide of tin; and oxide of zinc is used for *enlivening* the different tints, a property peculiar to the oxide of that metal, and the effect of which is greatly enhanced by the fact that it imparts no color to the glaze; it also improves the sulphur-yellow colors of the oxide of antimony.

As the property of communicating any desired color to glass is confined within certain limits of temperature, beyond which the tint varies, or is altogether destroyed, a certain classification of the colors becomes necessary, according to the reaction of the temperature upon their constituents. They are, therefore, divided into such as have the power of withstanding the most intense heat of the firing kiln, and which can be burnt in with the glaze—termed *refractory colors*, and those which afford no color at such temperatures, on account of the volatilization, or only a very imperfect tint—designated *muffle colors*. The latter require to be applied to the wares after the process of glazing has been completed, and afterwards fixed in a small furnace called the *muffle*, shown at Fig. 484M—and at a temperature far below the fusing point of the glaze or body of the ware, otherwise they would run and penetrate into the glaze. *Muffle colors*, being painted upon the ware in *relief*, can be distinguished by touch from the decoration in *refractory colors*, and impair by their projections the lustre and smoothness of the surface, besides being more liable to suffer and wear away by friction. It is worthy of remark also that the firing of *refractory colors* causes no increase in expense, while the burning in the muffle is a constant source of additional expenditure. The refractory colors are—

1. *Blue*, with cobalt.
2. *Green*, with chromium.
3. *Brown*, with oxide of iron, oxide of manganese, and perchromate of iron.
4. *Yellow*, with oxide of titanium.
5. *Black*, with oxide of uranium.

These pigments in the firing generally impart a very intense color, and can be used in very small quantities, which exert no liquefying action on the glaze, or on the mass of the ware. They may either be applied directly to the biscuit ware, or upon the glaze, the silicate of an alkali being used with them as a flux. *Muffle colors*

are incorporated with a great variety of fluxes, the most important of which are—sand or quartz, saltpetre, borax and boracic acid, felspar, potassa, soda, and minium or litharge.

Gilding is executed on porcelain in the usual manner, the gold being prepared in a pulverized form, and pre-

Fig. 484M.

cipitated from its solution in nitrohydrochloric acid by protosulphate of iron. The brown powder thus obtained is washed, dried, mixed with about one-tenth of oxide of bismuth, and rubbed up with thickened oil of turpentine. This gold mixture is then applied with the brush and fired in the usual manner, when the oxide of bismuth forms a flux with the surface of the glaze, and the gold becomes firmly attached. It has a dull yellow appearance upon leaving the *muffle*, and requires to be burnished with an agate to restore its metallic lustre. *Platinum Black*, or *Platinum Sponge*, is applied in precisely the same manner as the metallic gold. A preparation of gold, held in complete solution by oil of turpentine, is used for gilding at Meissen. It is not so durable, however, as that obtained by the ordinary process.

As a certain amount of heat is necessary in the muffle for the successful firing of the more fusible colors and gilded ware, pyrometrical tests are applied to ascertain the necessary temperature. A very convenient test is afforded by the variation of color through which the gold purple passes when submitted to a gradually increased temperature, six gradations being marked by the porcelain painters, corresponding to the six most important changes in temperature. Thus a piece of porcelain painted with the prepared purple of cassius, and exposed to the muffle, gradually becomes—

		Degrees of Fahr.
Of a dirty-brown red color,.....	corresponding to gilding upon colored grounds,.....	1148°
Brick-red,.....		
Brick-red, passing into rose, and red on the edges and thinner parts,.....	" retouching,.....	1474°
Rose-color, passing into purple,.....	" easily fusible colors,.....	1652°
Rose-color, passing into violet,.....	" gilding upon glaze,.....	1688°
Rose-color, passing into deep violet,.....	" gilding upon plate edges,.....	1742°
Violet has become lighter,.....	" more difficultly fusible colors,.....	
Rose-color has disappeared, and the violet become very pale,.....	" dull gilding,.....	1832°

The *watches* introduced into the muffle for the purpose of ascertaining the temperature, are covered both with gold and color, in order to ascertain the degree of heat at which the gold becomes attached without altering the tints of the hues. Painted porcelain generally requires retouching and passing through the muffle two or three times, the results of the first firing always being more or less imperfect. The principle of the muffle pyrometer used at Sèvres depends upon the expansion of a silver rod, which, melting at 2282° — 1000° Celsius—does not register quite up to that temperature. At this manufactory, also, an ingenious method of removing faults in the painting is adopted previously to retouching them. A brush, dipped into liquid hydrofluoric acid, is traced over the parts, which are afterwards washed with water; the etched part appearing perfectly white, and only slightly corroded, is in a very favorable condition for receiving the fresh pigments.

The semitransparent nature of porcelain has been made subservient, within the last few years, to the production of elegant imitations of paintings, and termed *lithophanous* pictures or transparencies, from *λίθος*, stone, and *φαίνω*, I shine through. The porcelain plates are constructed thicker in some parts than others, according as it is intended to produce greater depth of tint, or otherwise. When a plate thus contrived is held against the light, the thicker portions appear shaded compared with the rest; and if the blending has been arranged with care, representations of exquisite softness and gradation in tints are obtained. The manipulation and firing are, however, attended with considerable difficulty.

Some very interesting and important experiments have been made by BROGNIART and MALAGUTI, with reference to the nature of porcelain, and which also furnish valuable hints connected with its manufacture. Masses of porcelain clay, composed of different suitable materials, and affording the same per centage composition as the porcelain mixture adopted during the last sixty years at Sèvres, 58 silica, 34.5 alumina, 4.5 lime, and 3 potassa—were submitted to the different processes of manufacture with the following results:—

When chemically pure substances were taken, such as—1, Precipitated silica, in part fritted with the proper quantity of potassa; 2, alumina, perfectly free from potassa, prepared by precipitation from alum; 3, pure lime instead of chalk—the mass melted at the lowest degree of heat in the kiln to a spotted enamel.

Another specimen of the same mixture, with less frit, contracted in the biscuit oven eighteen per cent., and in the firing twenty-eight per cent.

When the kaolin was replaced by fire-clay, and the potassa was added, having been previously fritted with silica, a mass was produced which, after exposure to

the biscuit fire, exhibited the fluxed appearance of ordinary stoneware, and which when fired could scarcely be termed porcelain from its spotted nature and slight degree of transparency.

By using a similar mixture of plastic clay, in which a proportion of leucite, instead of the necessary amount of potassa, was present, a well-glazed porcelain was obtained, though somewhat spotted. When lime was employed in place of chalk, or the quartz-sand was replaced by flint, no alteration in the properties of the normal mass was observed.

These experiments show that it is by no means a matter of indifference of what materials or of what minerals the elements of the mass are composed, even though its relative proportions remain the same.

Fig. 434x.

Parian or *Carrara Biscuit Ware*, introduced some fourteen or fifteen years ago, is the finest description of biscuit made, and differing only from porcelain by the employment of a soft, more fusible felspar in place of Cornish-stone. In effect, statuettes and other objects made of this ware, present a great similarity of appearance with the beautiful marbles after which it is named. The general introduction of this art was due to a suggestion of the great sculptor JOHN GIBSON, to reproduce his *Narcissus* as a statuette in the statuary porcelain, and was first successfully carried out by the firm of COPELAND and GARRETT, the eminent manufacturers of Stoke-upon-Trent, under the artistic direction of Mr. THOMAS BATTAM, a gentleman well known as the director of the Ceramic Court at the Crystal Palace. The perfection to which the manufacture is now carried, is evidenced by the grace and beauty of outline of the

works both of ancient and modern art reproduced in this material by the Messrs. COPELAND, MINTON, WEDGWOOD, KERR and BINNS, RIDGWAY, MAYER, and other eminent potters. Outlines of two of these groups—the production of Messrs. COPELAND and GARRETT—are annexed; Narcissus, by GIBSON—Fig. 484N—the first Parian statuette ever produced, and executed for the Art Union of London; and the second, a reduction of Sabrina, by J. C. MARSHALL, —Fig. 484O. It is hardly necessary to add, that other eminent sculptors have lent their aid in the development of beautiful models in this material, so nearly approaching the true marble. In the *Parian* body the agreeable creamy or yellowish-white tint which it possesses is not due to any coloring matter mixed up with the ingredients, but is owing to the presence of a small quantity of oxide of iron in the clays and felspar, which during the firing forms with the silicic acid a silicate of sesquioxide of iron, imparting the color. The making of figures with the Parian body requires great care, knowledge, and skill, being cast in different parts, and afterwards united together. The *slip* for this purpose is in a liquid state, the deposit

tained in the slip, the mass contracts in the firing process no less than one-fourth of its bulk. Some of the ingredients composing the Parian bodies are given below:—

For vases, small figures, jugs, *et cetera*.

The beautiful perforations and network first introduced into porcelain statuary manufacture at Coalport, such as lace, drapery, *et cetera*, are made by a very ingenious and at the same time simple process, being a kind of incrustation of the original fabric, which, dipped into the slip, is afterwards allowed to dry, a deposit of slip being everywhere formed upon it. The subsequent process of firing destroys the original tissue inside.

In practice the process may be described as follows:—Upon a gypsum slab, over the surface of which a film of the fluid slip has been brushed, the piece of net is evenly spread out and a second coating of slip afterwards laid over the whole. The porosity of the gypsum absorbing the water leaves only the clay in a thin film surrounding the fibres of the net, which, when lifted, is wrapt around the statuette to be decorated, and placed in the oven. If it were not for this absorbing of the gypsum, the minute interstices of the lace would become filled up with the liquid and present a solid part when fired.

STONEWARE.—Under this denomination two varieties of claywares may be classed—*fine stoneware* and *ordinary stoneware*—differing essentially from each other in the nature of their constituents. The chief

Fig. 484O.

in the mould being allowed time to harden before removal; after which those parts which, from the softness and yielding of the mass might sink, are supported by props. From the large proportion of moisture con-

substances used in the manufacture of stoneware are the layers of pipe and plastic clay which lie above the chalk, and generally abound in the coal formations. The plastic clays, like the varieties of kaolin, must be considered as definite combinations of silica and alumina, probably $2 \text{ Al}_2 \text{ O}_3$, 3 SiO_2 , with water of hydration more or less contaminated with other mineral substances by mechanical agency. A distinguishing characteristic of these clays is the small quantity present of those mixtures of bases which tend to promote easy fusibility, the greater portion of the plastic clays being infusible. On analysis, these clays show from 1 to 4 per cent. of oxide of iron, from 0.5 to 2 per cent. of lime, a rather smaller amount of magnesia, and from 0.5 to 1 per cent. of potassa, ingredients not necessarily all present at the same time. In color the clays vary; passing from the most general one, white, to whitish-grey, or into greenish, rose color, or violet; at other times bluish-black or black. At a temperature of 212° only a portion of the water they contain is expelled; the other portion, amounting to 6.12 or 18 per cent., being held in chemical combination, can only be completely driven out at a red heat, the temperature at which the clay burns and loses its plasticity. At that temperature a chemical action occurs, the alumina being rendered much more soluble in acids than is the case with fresh clay. Thus, clay when burnt loses 44.3 per cent. of alumina in sulphuric acid, while fresh clay only parted with 23.4.

The plastic clays in general contain little of the undecomposed fragments of rock and coarser ingredients, but sand and finely divided silica are mixed with them in very varied proportions. In the analysis of thirty different varieties at Sèvres, the amount of silica was found to vary from forty-two to seventy per cent., alumina twenty to forty per cent., and of water between six and nineteen per cent., the remainder being oxide of iron, lime, *et cetera*. Plastic clay, after burning, is white or reddish from the presence of oxide of iron, the other colors arising from organic substances being eliminated in the fire.

Fine Stoneware.—The production of this ware is most extensively carried on in England at the potteries, where the manufacture has attained the highest degree of perfection. With it may also be included that known as Wedgwood jasper-ware—from its celebrated discoverer—and famous for its unrivalled production of cameos and medallions. As it is manufactured in great quantity and in almost every conceivable form, it will be treated of under *Wedgwood-ware*.

The mass composing fine stoneware is a mixture of plastic clay and a flux of a felspathic nature. The hard texture of plastic clay after burning, and the shrinking it undergoes, cause it to become very fragile, while the application of long and intense heat is necessary to produce that semifusion which is one of the characteristics of the ware. This semifusion is fac-

ilitated by the addition of the flux, which acts precisely in the same manner as in real porcelain; the chief external difference between fine stoneware and real porcelain being the almost entire absence of translucency in the former.

Mixture.—The mass composing the body of fine stoneware is more complex than that of common stoneware, and being harder and more brittle after firing than the latter, is distinguished from it by the term *dry body*. It is generally composed of *kaolin*, *plastic clay*, and *Cornish-stone* as a flux, sometimes the kaolin, and sometimes the plastic clay taking the preponderance; but the proportion of the flux generally amounts to fifty per cent. of the whole—a much larger proportion than in the true porcelain body. It is from this cause that fine stoneware, when subjected to the heat of a porcelain kiln, melts, and requires therefore a more moderate temperature in baking. The mass is much more plastic than that of true porcelain, a circumstance which enables it to bear a much larger proportion of a poor flux, such as felspar, than the kaolin. Fine stoneware may therefore be considered a substitute for real porcelain, the manufacture being cheaper, from the greater ease and facility with which it is fired, and possessing also the property of non-permeation by liquids.

Some of the proportions in mixing the mass are given below:—

White stoneware bodies for jugs, <i>et cetera</i> .	I.	II.	III.	IV.
Cornish stone,	80	40	100	30
Cornish clay,	20	10	20	10
Blue clay,	40	20	18	18
Flint,	20	—	40	2

with the addition of a little blue cobalt to whiten.

Mortar bodies.	I.	II.	III.	IV.
Cornish stone,	200	90	50	50
Blue clay,	80	80	25	20
China clay,	—	30	20	40
Glass,	—	—	1	—

These separate ingredients are all ground to a fine powder—see *Earthenware*—and mixed together with the greatest care, in order to increase the plasticity of the mass in working.

The wares are formed in a similar manner to that described under *Earthenware* by means of the *wheel* and *lathe*, or pressed into plaster of Paris moulds, when the irregularities of the outline render this necessary. Many kinds of this ware are decorated with *basso-relievos*, the manipulation of which will be found under *Wedgwood jaspers*. These bas-reliefs, from the more binding character of the material, are fixed on to the body with greater facility than is the case with true porcelain. Many varieties of stoneware are composed of a colored mass, care being taken that the metallic oxides used for that purpose are not applied in such quantities as to impart easy fusibility, or endanger the stability of the ware in firing. The ingredients in use for forming certain colors are given below:—

Colored stoneware bodies.

Sage—White stoneware body :—Stain—Oxide of chrome and cobalt.

Drab—White stoneware body :—Stain—Fifteen per cent. common marl, and a little nickel.

Dove—White stoneware body :—Stain—One per cent. manganese with one-fourth part per cent. cobalt.

Other colored bodies being merely modifications, according to the tints required. The after process of

firing the mass is much the same as that described under *Earthenware*.

Wedgwood Jasper-wares.—Amongst this celebrated description of fine stoneware, the manufacture of Mr. WEDGWOOD, may be enumerated those known as *jasper*, *terra-cotta*, *basalt*, *granite*, and *porphyry*; wares which, from the particular composition of their bodies, are capable of receiving the most exquisite degree of finish and delicacy in their manipulation, rivalling in beauty of form and chasteness of outline the art productions of the ancients.

One of the most remarkable of these bodies is the *jasper* or *onyx*, which presents to the eye a white biscuit of a porcellaneous nature, and which has the property of receiving, through its entire mass, by the admixture of metallic oxides, the same colors that those oxides would impart to glass or enamel in a state of fusion. This property, peculiar to itself, renders it applicable in a manner no less pleasing than extraordinary to the production of *cameos*, *portraits*, *vases*, and all subjects which require to be shown in relief, the ground being made of one color, while the raised figures are of the purest, most delicate white.

The composition of this jasper or onyx body may be given as follows, the blue color being imparted by the admixture of oxide of cobalt, in proportions varying from one-third of a part to one part per cent., or more, according to the depth of tint required:—

White jasper bodies.	II.	III.	IV.	V	VI.	
Sulphate of barytes, . . .	150	40	30	50	32	160
China clay,.....	35	—	—	15	10	60
Blue clay,.....	45	20	12	35	25	90
Flint,.....	35	—	3	10	8	40
Gypsum,.....	6	—	—	—	1	8
Cornish stone,	50	20	20	—	7	—
Bone,.....	—	—	—	25	—	—

The proportion of *stain* being one part of cobalt to from fifty to seventy-five parts of the body, according to the depth of color required. The various other colored jaspers are obtained by the addition of other oxides to the several white bodies.

The *green* jasper is obtained by the admixture of the oxide of chromium.

This jasper body resembles so nearly in appearance the glassy vitreous substance of the ancient gems, that it has become celebrated throughout the world for the beautiful imitations of medallions, cameos, and vases it is capable of producing. It constitutes also the dark-blue ground, with its gem-like surface, of WEDGWOOD'S copy of the Portland vase, a sepulchral urn of great antiquity, discovered in the neighborhood of Rome between the years 1623 and 1644. The careful investigation of this gem of art has pronounced the body of the vase to be formed of a transparent glassy structure of a deep amethystine hue, but which, when viewed by reflection, appears black and opaque, while the raised figures on its surface are white glass, of a sufficiently transparent nature to admit of the blue color of the ground tinting their form through the thinner parts, while the thick possess sufficient opacity to appear of a pure white. The examination both of the ground and bas-reliefs lead to the belief that the blue body of the vase when formed, and still red-hot, was coated all over as far as the bas-reliefs were intended to reach with the white glass, and the handles applied afterwards while in the same red-hot condition—a fact demonstrated by

the intervention of a layer of this white enamel between the body of the vase and the lower extremity of the handles, the upper portions being in direct contact with the vase itself. The figures seem to have been produced by a subsequent cutting away of this white coating down to the blue ground, after the manner of real cameos.

The extent to which the manufacture of imitative ancient gems was carried in the Wedgwood jasper body was enormous, and is again considerably upon the increase at the present time; the original purity and other pristine qualities being revived at Etruria, the seat of the manufacture, by the energies of Mr. GODFREY WEDGWOOD, the eldest son of the present FRANCIS WEDGWOOD, the descendant of the great JOSIAH WEDGWOOD. This, from the re-discovery, as it were, of the first jasper body, together with the possession of all the original models and moulds designed by FLAXMAN and others, renders it more than probable that the ware will again attain the high standing of former years, and that the mantle of the great WEDGWOOD will once more descend amongst his own people.

Manufacture.—In wares of this description the mass is frequently white, and only covered on the surface with a thin colored coating of the same body, the shrinking properties of the mass not being essentially affected by the addition of small quantities of the metallic oxides. The mass, after formation upon the throwing wheel in the usual manner, receives when sufficiently hardened the proper outline upon the lathe; and if a vase or other similar shape, such rims or fillets are turned as are intended to appear white upon the dark ground in the after manipulations. The piece is then taken into the dipping-room, where it is immersed in a tub containing the colored slip of a consistency approaching thick cream, and receives a thin even film over its whole surface. It is then allowed to harden until it is sufficiently firm to admit of being placed a second time upon the lathe, when a burnisher is run over it to give uniformity and smoothness to the surface; the blue dip, at the same time, being turned off, and exposing those portions intended to appear white, such as mouldings, lines, *et cetera*, produceable on the lathe.

The piece is then taken to the *decorator*, who affixes the various ornamentations intended to complete the design. Taking the vase in one hand, he with a small hair pencil moistens with water that portion of the surface intended to receive the pattern, which is affixed in its proper position by a very gentle pressure of the finger and the aid of a damp sponge; each separate ornament being added in this manner, until the whole decoration is complete. The piece is then sent into the oven to be fired in the usual way.

The ornaments in relief are obtained, like an impression from a seal, by pressure in a mould made of baked clay or plaster of Paris. The moulder sits at a bench with a number of these small moulds before him, a lump of the plastic material forming the body of the ware being placed at his side, and from which, by means of a small spatula, he separates pieces of the clay, and rapidly fills or presses them into three or four of the moulds. This done, he takes the one first

in order, and with the smooth flat end of his tool burnishes over the surface of the mould, removing the surplus clay, and causing the sharp-cutting edge of the die to give a clean sharp outline to the impressed clay, which, yielding slightly to the rubbing process by suction, leaves the mould, and is turned out on a slab for use by the decorator, who has to exercise considerable care and dexterity in preserving the sharp outline of the relief in its application to the ware. In the *original* WEDGWOOD fabrications, so much of the beauty of the piece depending upon this particular, the outlines were sharpened and restored by modellers before the ware was sent into the oven, producing such exquisite embellishments that now, sixty-five years after his death, connoisseurs are eager to purchase them at three times their original price. Those decorations, such as flowers, *et cetera*, which are not capable of receiving their form by pressure in the mould, are modelled by hand separately, and united afterwards piece by piece together. The other bodies of WEDGWOOD, which in composition resemble agate, jasper, porphyry, and other variegated stones of a vitrescent or crystalline fracture, are used largely in the formation of ornamental wares. These bodies are composed of various colored clays, placed in layers to represent when pressed together the several stones they are intended to imitate, care being taken that they shall not so amalgamate as to destroy the beauty of the imitation.

The *Basalt* or black Egyptian biscuit, so called from its resembling basalt in appearance and color, forms the mass from which the most esteemed forms of ancient Egyptian art are modelled, and which is enriched with bassi-reliefs both in red and white; many articles

of domestic requirements, such as tea-pots, milk-jugs, ink-stands, *et cetera*, are moulded in the same style from this mass. In composition it may be given as follows:—

Basalt or Black Egyptian bodies.	I.	II.	III.	IV.	V.	VI.
Blue clay,.....	200	330	200	—	100	—
Red clay,.....	—	—	30	500	—	500
Ochre calcined,.....	200	300	100	75	100	—
Iron scales—protoxide of iron,.....	—	30	—	—	35	—
Manganese,.....	60	80	100	75	40	100

Red body—terra-cotta ware.

Red marl very carefully sifted,.....	10 parts.
Common marl,.....	2 parts.

with the addition of ten per cent. of Cornish clay, if a light color is required.

The revival of painting upon vases and other similar articles in the manner of the ancient Etruscans, without the glossy appearance of ordinary painting upon porcelain or earthenware—an art lost since the time of PLINY—is due to Mr. WEDGWOOD, who, after careful examination of original Etruscan vases, finding it impossible to imitate the colors by *enamels*, devised other substances, termed *encaustic* colors, producing an entirely different effect, and without any of the glossy lustre of the enamels in the firing. This discovery at once enabled successful imitations of the ancient vases to be made in all their variations of light and shade, and of equal durability with the enamels, without the defect of a varnished or glassy surface. Encaustic colors are applied with great ease and certainty, changing but little in the firing, and have no tendency to run or spread on the design. The composition for certain colors may be given as follows:—

ENCAUSTIC COLORS.

White.	Black.	Green.	Blue.
Blue clay,..... 20	Egyptian black,.... 12	White slip,..... 12	White slip,..... 25
China clay,..... 10	White slip,..... 3	Blue slip,..... 1	Blue cobalt,..... 1½
Flint,..... 10	Blue slip,..... 3	Nickel,..... 1	
Cornish stone,.... 5			

These clays, finely ground and brought to the consistency of thick slip, are painted upon the wares while in their moist state, and before firing in the biscuit oven.

It is impossible to conclude this notice of the jasper wares of JOSIAH WEDGWOOD, without quoting some remarks upon the manufacture of pottery which conclude his catalogue—dated and published in 1777—remarks peculiarly applicable to the manufactures and productions of the present day. He says:—

A competition for cheapness, and not for excellence of workmanship, is the most frequent and certain cause of the rapid decay and entire destruction of arts and manufactures.

The desire of selling much in a little time, without respect to the taste or quality of the goods, leads manufacturers and merchants to ruin the reputation of the articles which they make and deal in; and whilst those who buy for the sake of a fallacious saving, prefer mediocrity to excellence, it will be impossible for them either to improve or keep up the quality of their works.

All works of art must bear a price in proportion to the skill, the taste, the time, the expense, and the risk attending the invention and execution of them. Those

pieces that, for these reasons, bear the highest price, and which those who are not accustomed to consider the real difficulty and expense of making fine things, are apt to call dear, are, when justly estimated, the cheapest articles that can be purchased, and such are generally attended with much less profit to the artist than those that everybody calls cheap.

Beautiful forms and compositions are not to be made by chance, and they never were made, nor can be made in any kind, at a small expense.—*Wedgwood.*

Fine stoneware in general is never glazed, though at times a glaze is produced spontaneously with the firing by a process called *smearing*, the inner surface of the seggars being coated with a glaze composed of—

The ingredients dissolved in hot water, and the seggars washed inside with the mixture.

This in part becoming volatilized during the firing, a portion of the alkali and oxide of lead is absorbed by the surface of the ware, forming a thin layer of glaze, both the surfaces containing silica appropriating a fair proportion of the vitrifiable bases. Sometimes a glaze containing a large quantity of lead or borax, is applied by the process described under *Porcelain* to either both or only one surface of the ware. When pigments are mixed with the glaze, colors—as is the case with yellow—are communicated to the ware which could not otherwise be produced. The firing of this kind of ware takes place in seggars, in furnaces of similar

description as those described under *Earthenware*, and often at the same time as wares of that description, being placed in those portions of the kiln where the temperature is highest.

Varnished and Larva Ware.—Other kinds of wares manufactured in Germany at Pirna and Saargemündt, and recently brought into extensive circulation for ornamental purposes, may be classed under fine stonewares, and possess a mass exhibiting a striking resemblance to porphyry or jasper, and capable of receiving the most delicate and refined forms in manipulation. The ware manufactured by UTZSCHNEIDER at Saargemündt exhibits several peculiarities—the contraction in the firing amounting to twenty per cent., while the mass is composed of three local varieties of clay, partly ferruginous, and quartz. The body, which is not glazed, but ground after firing with emery and polished with tripoly, requires the same precautions in the manufacture as that described under *Fine Stoneware*. The ware manufactured at Pirna on the Elbe has likewise a colored body, the chrome green and black masses being without glaze and dull; while the ochre-yellow mass of other varieties is often concealed by a coating of very brilliant varnish color, very different to potters' pigments, from its soft nature, fatty lustre, and easy destructibility in the fire, being, in fact, an oil paint. This varnish is laid on very smoothly and with great care, to preserve the outlines of the ornaments in relief, and afterwards when dry covered with a thin coating of copal varnish. It is secure from injury by hot water, but neither withstands abrasion by the knife, or use over the fire. Fine stoneware, as a general rule, does not stand well against heat or sudden changes of temperature.

The relative values of plastic clay for the manufacture of *fine* and *common* stoneware, with and without glaze may be here given—

STONEWARE GLAZED.

From which tables it appears that stonewares may be divided into two classes—those containing from seventy-five per cent. of silicic acid, and others of from sixty-two to sixty-six per cent. Experiment further proves that an excess of silica in the body is very favorable to the production of a good glaze.

Ordinary Stoneware—one of the characteristics of which, namely, the semi-fused state of the mass, results from the much stronger heat of the kiln, and not from the addition of flux. The composition is more simple; only one addition being made to the plastic clay, which, having no tendency to shrink in the furnace, prevents the clay from any very serious contraction, the amount of which varies, as in the finer stonewares, from eight to ten per cent.

As the plastic clays generally possess this property of contraction in a high degree, objects formed from them without this addition and tolerably thick in the sides, infallibly crack in the firing.

The action of such additions has been determined experimentally upon the plastic clay of Dreux mixed with—

	Contracts,
10 per cent. ground fragments of stoneware,	15 per cent.
25 “ “ “ “ “ “	5 “

No addition, clay in natural state,10 to 11	“
No addition, clay purified by suspension in water,.....	17 “

From which it appears that the plastic clay under experiment contained in its natural state an admixture of some substance that diminished its power of contraction, and which was removed from it by decantation in water, increasing the contractile power. In the potteries a very important practice is adopted, that of combining together the several kinds of clay found to produce the best result in the fire, both as regards the contraction, color, and refractory nature of the mass.

In the manufacture of ordinary stoneware vessels, such as jars for preserves or pickles, milk pans, *et cetera*, the process of decanting the clay from water would be too costly, and the coarser impurities which might interfere with the formation of the ware, are therefore either removed by repeated kneadings and treading out of the mass by manual labor, or separated by passing the clay through the *pug mill*—see *Earthenware*.

The low price at which these wares are purchased in the market necessitates the adoption of the most simple modes of forming and manipulation; they are generally, therefore, thrown upon the potter's wheel, already described under *Porcelain*. From the large dimensions of the vessels that sometimes require to be formed, increased facilities are given to the workman for producing greater persistence in the rotatory motion of the wheel, and using larger plates or discs for the support of the mass. These arrangements are shown in Fig. 484P. The cast-iron wheel, R R, is connected to

the hollow shaft, A A, carrying the head or disc of the lathe by double spokes, s s', s s'. The top of the hollow shaft at a is fitted with an iron cup, into which the top bearing of the supporting axle running through the centre works, while the lower extremity of the hollow

Fig. 484P.

shafts, m m, being of iron, rests upon the conical support, b, of the axle. The wheel and shaft, therefore, turn with little friction, being suspended after the manner of a ship's compass. For the greater convenience of the workman, who sits at the bench, g, the surface of the disc, B, is placed below his level. Impulse is given to the iron wheel by a pointed rod, the rotatory motion lasting long enough for one operation, and the high degree of plasticity in the mass being of great assistance. The help of an assistant to turn the wheel is therefore only required when a great amount of resistance has to be overcome. Vessels of a wide bulging shape and of moderate dimensions are first thrown in the form of a hollow cylinder of the intended height and width, the contraction being afterwards effected by pressure against the mass in its revolution; larger vessels of similar form are put together from two halves separately formed, the handles, *et cetera*, which are made by hand, being simply pressed on to the mass. In the firing of common stoneware, horizontal kilns or furnaces are used, in which the draught has a direction more or less parallel with the floor. It is only in kilns of this construction that the wares can be placed alongside of each other, instead of being piled up in columns or bungs. By such an arrangement of draught, however, the heat of the furnace is very irregularly distributed. All common stoneware in the firing is exposed directly to the action of the flame, the nature of the surface not rendering the protection from dust and scratches by the use of seggars necessary.

The kiln—Fig. 484Q—is in general roughly constructed, the grate, r, separating the ashpit, c, from the hearth, B. The portion of the kiln where the wares are fired is shown at A, an elliptical arched dome, a a, covering the whole. The draught is regulated by a plate covering the aperture, g, the fire being supplied with fuel through e. By this arrangement the flames carried by the draught pass through the apertures, i, i, in the wall, m m, to the chamber containing the wares, from which they enter the chimney, o, by the holes, n n. The wares are introduced into the kiln by doors which

are bricked up during the firing. At Lambeth, near London, the kilns assume a vertical character, are about ten feet in diameter in the baking chamber, and

Fig. 484q.

eleven feet high to the centre of the crown; they have five fire grates, each twelve inches wide and three feet long, containing five or six fire-bars, a bag or chimney flue about five feet high being placed opposite each fire. Fig. 484R represents a section of one of these

Fig. 484R.

kilns: A is the baking chamber; C the fire-grate; D the ash-pit; and F the bag or chimney, the wares being introduced by the opening, B, bricked up during firing. In the kilns used for common stoneware, the smaller articles are placed at the bottom part of the kiln,

in square cells formed by placing stout tiles upright in rows, with others laid horizontally upon the top—the heavier and coarser portions of the ware being placed upon the top. These cells or boxes generally occupy one-half the height of the kiln. Great care and experience is required in the management of the fires, as, if too little air is admitted, the smoke and gas will be imperfectly consumed, and the wares discolored; while, on the contrary, if air enters too freely the heat is not sufficiently intense to vitrify the clay. The heat of the furnace often attains 120° Wedgwood, this ware requiring the most intense heat, after real porcelain, of any kind of pottery.

Common stoneware, being sufficiently dense and vitreous in its mass to be impermeable, requires no glaze, but by a very cheap and simple process the dull surface is made smooth and lustrous. A natural glaze, or the waste from other branches of the manufacture, is used, ground to a fine powder, and sifted or sprinkled over the moist ware in a thin stratum; it is afterwards burnt on in the process of firing. Iron slag is generally used for this purpose, the large proportion of the oxides of iron and manganese which it contains rendering it of easy fusion.

Salt-glaze.—The simple and old-fashioned salt-glaze is also of very general application. Its discovery, dating about the year 1680, is said to have been accidental, the tradition being that at Stanley farm at Bagnall, about five miles East of Burslem, the servant of Mr. JOSEPH YATES was boiling a strong brine of salt, to be used for curing pork; during her temporary absence the liquor boiled over the sides of the earthen vessel used for this purpose, and, becoming very hot, the vessel on cooling had a glazed surface. A Mr. PALMER, who carried on a small pottery about a mile from the farm, availed himself of the hint, and commenced a manufacture of ware glazed with chloride of sodium, which was readily procured from the salt wyches—Middlewich and Northwich in Cheshire. The process of glazing with salt takes place towards the end of the firing, when salt is thrown into the kiln through particular apertures. The temperature of the kiln being considerably above a red heat, volatilizes the chloride into a vapor which, filling the chamber, surrounds the wares, and causes a reaction to take place with the silica of the mass. These two substances, silica and common salt, only act upon each other in the presence of aqueous vapor, and which is always present in the flame of the furnace. With the sodium of the chloride, the oxygen of the water produces soda, which enters into combination with the silicic, while the hydrogen unites with the chlorine, and is evolved as hydrochloric acid— $\text{NaCl} + \text{HO} = \text{NaO} + \text{HCl}$. The glaze is, therefore, a soda glass, and exists as a very thin coating upon the surface of the wares. Clays which contain less than fifty per cent. silica are without action, and do not decompose salt. A brown color is

communicated to the wares by throwing into the furnace, during the glazing process, substances which afford a large volume of smoke, such as the bark of the birch tree.

Common stoneware generally varies in color from grey to bluish-grey, yellowish-red, brownish-red, and brown.

The manufacture of stoneware by *moulding*, has recently been brought to great perfection, and most of the vessels used in chemical laboratories are formed in this manner, the smaller articles being remarkably thin and light. The larger vessels for chemical works, such as acid bottles, *et cetera*, are sometimes of enormous dimensions, and constructed to contain from one hundred to three hundred gallons. The agreeable brown color of these vessels is produced by dipping them into water containing oxide of iron in suspension.

The principal seats of the manufacture of common salt-glazed stoneware are at Glasgow, Lambeth, Belper, and Nottingham; the other variety of common glazed stoneware being produced at Bristol and Chesterfield, while the fine stoneware manufacture is almost exclusively confined to the neighborhood of the Staffordshire potteries. On the Continent the manufacture is extensively carried on at several places, particularly at Buntzlau in Silesia, and at Vallendar, on the Rhine opposite Coblenz, where two kinds of clay are worked—a blue clay for grey ware, and a yellow clay for red ware. At Buntzlau the wares are colored brown by immersion into a solution of marly clay after the manner of a glaze.

EARTHENWARE.—Under the term *earthenware* are embraced many varieties of pottery, which in fracture have all an earthy appearance, are perfectly opaque, and are coated with a soft, easily fusible glaze,

containing lead or borax. But, notwithstanding they all possess these characteristics, the modifications and varieties of this ware are more numerous than those of any other kind. The several kinds of clay—plastic or pipe-clay, potters' clay, and marl, to which quartz is sometimes added—enter into the composition of all earthenware. The absence of any real flux, and the circumstance of its being fired at a temperature which precludes the partial or entire fusion of any one of its constituents, distinguishes earthenware from porcelain and stoneware, while the greater care bestowed upon the preparation of the materials, and consequent greater purity of the mass, together with the general absence of color, are sufficient to mark the distinction between this and delftware.

Fine Earthenware.—The English manufacture may be selected as the type of this ware; it is composed essentially of a mixture of plastic clay and quartz, and is, therefore, more refractory, harder, and denser than the delftware, the chief ingredients of which are potters' clay and marl, and which is in consequence soft and calcareous. Fine earthenware again is always coated with a transparent glaze; the commoner sorts with enamel, producing the favorite *Majolica* ware. Neither kinds, however, are fitted for culinary use, as they either split when exposed to heat, or the glaze becomes cracked and crazed.

The crude materials used in England in the manufacture of fine earthenware, are Cornish stone and China clay, a kind of kaolin brought from Cornwall, two varieties of plastic clay, both of which burn white, and chalk-flints. That class called *ironstone china* is made from a mixture of plastic clay, kaolin, Cornish stone in excess, and silica, the formula of which is subjoined:—

IRONSTONE CHINA BODIES.

	I.	II.	III.	IV.	V.	VI.
Cornish stone	180	200	700	600	600	400
China clay	120	150	500	600	100	250
Blue clay	60	100	300	—	180	150
Flint	80	120	250	400	60	75

A small proportion of cobalt blue is added as a stain to whiten the mass.

These are the three principal modifications into which this class of claywares may be subdivided, leaving innumerable others of an intermediate character. Mixtures for the mass of the following varieties are given below:—

Cornish stone	15	10	100
Oxide of chrome	3	3	Turquoise stain.

	Cane.	
Grey marl	120	The marls should be very carefully sifted through fine lawns, and if ground finely in a pan at the mill, the body will be much improved. This remark applies to all colored bodies.
Blue clay	13	
Flint	6	

These porous bodies are all fired in the glazing oven.

Preparation of the Material for forming the Mass.

The flints are prepared for the grinding process by crushing in their calcined state under the stamping-mill—Fig. 484s—which consists of a series of upright beams, *a, a, a*, of wood, shod at their lower extremities with heavy iron shields, *b, b*. These beams being alternately raised in a vertical direction by means of projecting pins, *c, c*, catching the arms of a revolving drum, *d*, fall with great force into a long narrow trough, *f*, placed in a horizontal direction underneath, and having its bottom formed of perforated cast-iron plates, *m*, through the holes of which the broken calcined flints pass, and are then ready to be conveyed to the block-mill.

The mill room where this grinding process takes place is fitted with a number of circular vats—Fig. 484t—from ten to twelve feet diameter; the bottoms of which are paved with square blocks of a very hard stone. These vats are fitted with arms in the same

manner as the mixing vats described under *Porcelain*. Blocks of stone weighing from ten to fifteen hundred-weight are placed against the arms, which are driven round by machinery. Into these vats the broken calcined flints are thrown, and water is introduced to prevent the escape of the finer particles of dust, which would be very injurious to the workmen. By this process the flints quickly acquire a state of minute division. After a period of about twelve hours the contents are run off through troughs into washing tubs or vats, where the coarse or heavier particles subside, the fine liquid flint passing into spacious reservoirs built and paved with bricks, and which are furnished with plugs, to enable the workmen to draw off the first water with which the grinding process took place, and bring the flint into a state fit for use.

The *Cornish stone* is brought from Cornwall in masses for the purpose of being ground and prepared, but without the process of calcination, and is used in

the bodies, besides being a most valuable ingredient in the composition of the glazes.

The process of grinding *glazes* is similar to that of

durable than the materials formerly employed, whilst, from the purity of its substance, and the entire absence of any injurious ingredient, the flint slip is left pure and free from admixture caused by the abrasion of the mill-stones. When by friction the *pavers* or *runners* have become too light, they are calcined with the flints, and afterwards ground up with them.

To increase its plasticity, the China or Cornish clay is mixed with as much blue clay as the quality of the ware admits. Where machinery is employed the lumps of clay are thrown into the blending vat, and stirred up with water, as already described under *Porcelain*. The liquid with the clay in suspension is then decanted, and passes into vats in the *mixing* or *slip house*—Fig. 484u. The clays are brought up by a lift to the floor of the

Fig. 484s.

flint grinding, but the vats or pans employed are generally of smaller dimensions. The requisite machinery not being erected at all the manufactories, the potters are usually supplied with the materials prepared ready for use, by mills established in the localities where this process is carried on.

A species of stone, which has been termed *Lagnatia quartzite*, and is found in Scotland upon the estate of

room where they are macerated by water, and pass into the tubs, *a* and *b*. The China clay, *a*, is brought to the standard of twenty-six ounces to the imperial pint, and that at *b*, containing the Dorsetshire or blue ball clay, to the standard of twenty-four ounces; the ground flint contained in the trough at *c* is likewise brought to the standard of from thirty-one and a half to thirty-two ounces, while the Cornish stone at *d* is of the standard weight of from thirty to thirty-one and a half ounces to the imperial pint. The China clay and blue ball clay having been admitted into the tanks, *e* and *f*, severally, in the proportions marked upon the gauge rods, *s s*, are united in the mixing cistern, *g*, the blue ball clay passing by the trough, *n*. The relative proportions by measure of Cornish stone and flint are now added, and mixed with the mass, which then passes into the trough, *t*, furnished with plugs and holes, *c' c' c'*, in its bottom, immediately over a set of fine silken sieves, *a' a' a'*, fixed in a frame, *p*, to which a sifting motion is imparted by attachment to the eccentric and rod, *d'*, worked by the engine. This lateral to and fro motion of the sieves cause a complete filtration of the slip into the tank, *h*, all the coarser impurities being left behind. From this tank, *h*, it is conveyed by the pump, *j*, and spout, *k*, into the trough, *e'*, where it undergoes a second and similar process of filtration through finer sieves, falling into the reservoir, *i*, and is conveyed away by the pumping apparatus, *m*, to the purifying machine, and for conversion into *slip* of the proper degree of consistency for working.

Fig. 484r.

Ardsheal, Argyllshire, has been recently introduced by Mr. MILES LOCKHART into the Staffordshire potteries for the purpose of grinding the flint. Being composed almost entirely of pure silica, it is harder and more

The *purification* of the slip by the abstraction of all particles of iron which have become incorporated with

it, from the abrasion of the iron hoops of the mill during the process of grinding, is one of great importance,

as were these impurities to pass with the mass through the process of firing, the iron, being converted into an

Fig. 484u.

oxide, would produce a brown or yellow stain upon the white surface of the ware. A clumsy and expensive method is frequently used to extract these par-

iron removed—a work of extreme labor and time, in consequence of the electricity of the magnets remaining constant. Greater simplicity, economy, and cer-

Fig. 484v.

ticles from the mass, by placing in a box a large number of small horseshoe magnets suspended upon a frame. The slip or glaze, as the case may be, is poured by an attendant into the box, and the frame containing the magnets afterwards agitated to bring the slip into contact with them; by this means the iron particles are attracted to the poles of the magnets, which are afterwards taken out one by one from the trough, and the

VOL. II.

Fig. 484w.

tainty have been given to this operation by Messrs. HOLMES and CORDON, who have recently patented an invention which, by the application of electric currents for inducing magnetism in soft iron, effectually purifies the slip or glaze from all such particles in a much shorter time, and at a great saving of expense to the manufacturer. One form of the apparatus is shown at Fig. 484v. *a a a*, are a series of coils inclosing the electro-magnets, *b b', b b', c c', c c'*, the coils being placed in such

5 M

a manner that the induced magnetism in the alternate poles of each set shall be of an opposite nature—Fig. 484w; the arrangement of the North and South poles is shown at *a* and *b*. The slip, in its passage through the machine, comes into contact successively with the several poles of the magnets; and the particles of iron being attracted by them, the slip is thoroughly cleaned from iron by the operation. The apparatus is placed in a strong box, *E*, with two apertures, *F* and *H*, for the passage of the slip through the machine.

The slip, which is now much too liquid, passes into the slip-house for consolidation in troughs of brickwork from eighty to one hundred feet or more in length, and about four feet wide by fourteen inches in depth. The fire, placed at one end, passes by means of flues under the bottom, which is constructed of tiles, into the chimney at the further end, by which means the whole of the heat is economized. The slip, upon reaching the boiling point, throws up a dirty scum, which is scooped off, the tumultuous ebullition preventing the separation of the particles, and securing the uniform mixture of the mass. This process requires about eighteen hours, care being taken to prevent any portion of the mass from burning during the evaporation.

In extensive manufactories where machinery is used, the beautiful apparatus patented by Messrs. NEEDHAM and KITE, for consolidating the slip by pressure, is being introduced, and is a decided improvement upon the old process of evaporation by heat.

Fig. 484x.

The machine—Fig. 484x—constructed of stout wood, in the form of a rectangular mass, is composed of a series of separate chambers or compartments, *a a a*,

bolted together by iron clamps, *b b*, in pairs, and forming the mass, *A B*. These separate compartments are each fitted up with a series of small wooden grooves or channels, *d d d'*—Fig. 484y—sunk half an inch below the level of the frame, *a a*, and having a canal or passage, *b b*, cut top and bottom of the passage of the

Fig. 484y.

water pressed from the slip through the holes, *c c*. By this arrangement each pair of frames when placed together will have a space between the grooves of one inch, into which the slip is forced by means of the connecting pipes and apparatus, *E*, each pair of frames having its separate supply pipe, *e*. The interior of the chamber is prepared for the reception of the slip by the insertion of a strip of fine hempen cloth, *f f*, the edges being wrapped and folded up to form a large bag, and the nozzle, *n*, for receiving the supply pipe, *e*, being permanently fixed on the double fold of the cloth. The weight of the bag is supported by the

hooks, *g g*, upon the upper portion of the frame. The machine being screwed up tightly by the rods, *b b*, the pressure is brought on by the pumps, and the water passes out through the fibres of the cloth and grooved channels, leaving the slip in the form of a thin, solid, compact, and plastic sheet of clay. The time required for the operation varies from an hour to two hours and a half according to the composition of the mass, the charging and discharging of the machine occupying an hour. Each machine can produce at the rate of four tons of prepared clay in the day. In order to strengthen the fibres of the cloth, and to enable it to with-

stand better the pressure and abrasion of the grooved surfaces of the chambers, it is dipped into a solution containing half an ounce of alum to a gallon of water,

an operation found greatly to increase its durability and resistance to wear and tear. Some statements of the expense and performance of these machines, compared with the old process of evaporation, are given below:—

COMPARATIVE COST OF CONSOLIDATING THE CLAY FROM THE SLIP.

By the Old Evaporating Kilns, over a period of six months.			By Needham and Kite's patented process, over a period of six months.		
1000 tons clay at 1s. 4d.,	£66	13 4	1000 tons clay at 3s. 6d.,	£175	0 0
Wear and tear of kilns,	32	0 0	Milling, at 4d.,	16	13 4
750 tons coal at 4s. 9d.,	178	2 6	Steam-power,	20	0 0
			Patent right per ton 6d.,	25	0 0
				£236	13 4
			Saving,	40	2 6
				£276	15 10

The cost of preparing the slip is in each case 8d. per ton.

The slip in this state passes through the *clay* or *pug-mill*—Fig. 484z—in order to bring the mass to a

Fig. 484z.

uniform consistency. The mill consists of a circular iron vat or cylinder, *a a*, bound together by iron hoops, through the centre of which the iron shaft, *b*, revolves, carrying with it several horizontal arms, *c*, armed with the sharp blades, *d*; these are fixed in a horizontal position, and inclined at a certain angle; by this arrangement the clay in its passage through the mill is cut up and forced out at the aperture, *s*, the mass constantly sinking as it is supplied with fresh clay from above, and separated as it issues from the machine, by means of a fine wire, into blocks, which are carried away to the store house for the process of *ageing*—see *Porcelain*. Before the mass is placed in the *thrower's* hands it under-

goes a further state of preparation, termed *slapping* or *wedging*, by being forcibly thrown upon a strong slab of plaster of Paris. The workman then divides the mass, and the piece cut off is again brought down with considerable force upon the other portion, a continual dividing and slapping of the mass being continued until the whole is of a perfectly homogeneous texture; at the same time care is taken not to cross the mass, but to *slap* the pieces together in the relative position from which they were cut, as, if this precaution were not observed, the ware would afterwards contract unequally in the firing. From twenty to twenty-five blows are given to the mass before it is sufficiently homogeneous for manufacture.

Throwing.—From the much greater plasticity of the mass used for earthenware, the operation of throwing upon the wheel is one of greater rapidity than is the case with the manufacture of either porcelain or stoneware, an experienced *thrower*, assisted by two boys, often producing as many as from twelve hundred to fifteen hundred eight-inch basins in a working day of ten hours; while between two thousand and three thousand of the small round ink bottles may be produced in the same time by a lad and his assistant. This extreme facility in the manipulation is certainly one of the principal reasons for the low price of the ware. The potter's lathe, in its general form, where machinery is not employed, is shown at Fig. 484AA, and consists of a fixed table, *a*, carrying an upright shaft, *b*, to which the *throwing* disc or head, *d*, is fixed for receiving the

Fig. 484AA.

mass of clay. *e* is a pulley fixed on to the shaft with grooves of different diameters, and receives motion from the driving wheel, *f*, by a cord passing under the

guide pulley upon the frame, *g*. The workman, seated upon the bench, *h*, regulates the velocity of his disc in the shaping of the mass by corresponding signals to the assistant who turns the wheel, *f*.

In the manufactories of WEDGWOOD and COPELAND, the lathes are driven by engine power, the arrangement

for regulating the speed, *et cetera*, being shown at Fig. 484BB. *a* and *b* are two conical drums, connected together by the belt, *c*, and to which motion is communicated by the driving wheel, *d*. The thrower sits at his table, and the axle, *e*, carries the disc, on which are placed two pulleys, *m*, *n*, one fixed, the other loose,

Fig. 484BB.

in connection with the drum, *b*, by means of the strap, *f*. The revolution of the lathe is thrown off and on by the treadle, *h*, under command of the operator's foot. The speed of the lathe is regulated by the assistant, who elevates or depresses the belt, *c*, upon the drum, *b*, by means of the winch and carrier, *s*, through which the strap works.

The *baller*, who prepares the mass for the *thrower*, is shown at *D*. Each piece is weighed when the vessels require to be of a uniform size, a stroke or two of the hand being given before it is pressed into the balls, *r*, ready for use by the thrower, who, after the formation of the vessel, dexterously separates it at the base from the disc by a fine brass wire, and places it on a board, where it remains until the mass becomes sufficiently firm to bear without injury the subsequent processes of turning, handling, *et cetera*.

Turning.—This manipulation requires considerable dexterity on the part of the workman, to avoid destroying or fracturing the piece whilst turning it to the requisite size, thickness, and shape, and presents also numerous opportunities for the exercise of skill, taste, and genius in giving to the several parts the prominence required, and to the whole the degree of elegance suggested by the pattern.

The common horizontal lathe resembles that in use for wood turning, and is generally set in motion by

male or female assistants, who by practice become remarkably apt in adapting the velocity of the motion to the requisitions of the turner, and at the same time perform all the necessary attendant operations, such as stamping the goods, and bringing them to or from the lathe. The vessels are fixed upon the head-stock of the lathe by insertion upon a chuck of a tapering form, which easily adapts itself to the inner surface of the vessel. The engine-lathe, turned by steam power—Fig. 484CC—has the speed regulated by the gauge, *b*, shifting the position of the band upon the driving drum, *a*. The motion of the lathe is reversible by the lever, *c*, changing the position of the driving belt from the direct motion pulley, *d*, to that of the reversed one, *e*. This retrograde motion is required for the final operation of smoothing, solidifying, and polishing the vessel after turning.

The turner's tools are of iron, thin, and well forged, about eight inches in length, and varying in breadth from a quarter of an inch to two inches, the cutting end being turned up at a right angle about half an inch, and made sharp and level upon the grindstone. All wares that are not circular in section, and such as are ornamented with bas reliefs, are made in plaster moulds, into which the mass is pressed with a sponge, *et cetera*. Thin vessels are made at the wheel, with the assistance of plaster moulds and tools, as already

described. When simple forms are required in great quantities, the hand of the moulder has lately been replaced by machinery, more particularly in some of the Northern potteries about Glasgow, Newcastle-upon-

Fig. 484cc.

Tyne, and Yorkshire. Fig. 484DD represents a form of the apparatus in which the cups are formed by means of the plaster mould, *b*, giving the exterior form, while

Fig. 484DD.

the tool, *e*, gives the interior shape. The plaster mould is fixed in its proper position upon the head of the disc by the iron ring, *a a*, in such a manner that its centre corresponds exactly with the point of the tool. The mould is brought into revolution by means of a treadle, while the tool, *e*, counterpoised by the

weight, *d*, is lowered to the proper distance through the guides, *i i*, by means of a second treadle. When a ball of clay is placed in the mould, and the treadles moved, the tool, *e*, descends into the revolving mass of clay and bores a hole, forming a cup, the thickness of the sides of which will correspond to the distance at which the tool, at its lowest point, is separated from the sides of the mould. When the forming is finished, for which a few seconds suffice, the treadles are set at liberty, and the mould brought to a state of rest; the tool being raised up above the mould by the weight of the counterpoise, *d*. The mould, with the finished piece, is then exchanged for another, and the operation repeated. A machine of this kind can be worked by female labor at a less cost than that of experienced moulders.

Handling, et cetera.—These manipulations are performed, for the better class of wares, by moulding in the same manner as that described under *Porcelain*, while for handles of a less ornamental nature, recourse is had to a small machine, called the *squeezing box*. This consists of an iron cylinder, *a*—Fig. 484EE—about six inches in diameter, and twelve inches deep, the

Fig. 484EE.

bottom of which has a hole, into which a piece of lead, *b*, is inserted, pierced of the size and section of the intended handle. The upper edge of the cylinder carries a strong iron frame, *c*, into which works a screw plunger, *d*; this, upon depression, forces the clay through the aperture in stripes of the proper form, and which afterwards, when cut into lengths and bent as required, are left to acquire their proper consistency before application to the wares. In this operation the handler cuts away from the edges or ends all superfluous clay, and, after moistening with slip the parts of contact, presses them gently against the body of the ware; they are afterwards trimmed with the knife to remove all superfluous matter. The vessel is then rubbed over with a moist sponge to remove all dust, previous to drying and placing in the seggars for the baking process.

Pressing, or hollow-ware squeezing, is a more laborious manipulation connected with this branch of manufacture.

The clay having been prepared by beating with the bat upon the gypsum slab to the proper thickness and dimension, is placed upon one of the sections of the mould, and with a moist sponge well worked into every part. All the sections being thus lined with clay, the edges are trimmed, and the parts of the mould carefully placed together, and secured in their position by a strap passed round them. The presser then passes his finger up every joint, so as to make a groove, into which a thin roll of clay is inserted, and worked into the mass by the finger, and smoothed with moist leather. All marks are removed with a sponge moistened with slip, and the inside is afterwards washed with clean water and a sponge. The mould and its contents are then set aside until firm enough to receive polish with a flexible horn plate. The article is afterwards removed from the mould, trimmed and polished with proper tools, to remove all appearance of seams, and the handle, spout, or other ornamentation, added in the usual way before baking. One mode of decoration which may be here described consists in the formation upon the ware, while in the lathe, of rings and devices in various colors. This decoration is produced in different ways. When an inlaid pattern in various hues, the workman, while the ware is in the plastic state, and revolving upon the headstock of the lathe, impresses the pattern upon the surface by a roulette, and afterwards blows through a fine tube, out of a bottle, thick colored slips into the several sunk parts, the bottles containing the slip being furnished with a mouth-piece and tube for that purpose. The surplus colored clays being afterwards turned off in the manner described under *Fine Stoneware*, the various inlaid rings of color are produced. When a marbled appearance is required, the tinted mixtures are placed in separate compartments of one vessel furnished with a spout in connection with the several chambers. On their exit from the vessel, all the colors flow out in a single stream, but unmixed with each other. This stream flowing upon the ware causes a waved or variegated appearance according to the regularity of the motion given to the piece, and articles so decorated, are commonly termed *depped* and *mocha* ware. All these colored clays require to be in the *slip* state, and not of an oily nature. The wares are afterwards fired and glazed as usual, according as the nature of the operation has been performed while in the plastic or biscuit state. A pleasing arborescent effect is sometimes given to these wares by a mixture of tobacco water, with manganese, nickel, oxide of iron, and a small quantity of cobalt, dropped on to the soft colored slip surface of the ornamentation.

Firing.—The temperature at which fine earthenware is baked being much higher than that required for the glaze, renders it necessary that vessels composed of this substance should be fired twice. At the first firing

the ware is completely baked, or converted into biscuit, the glaze only being burnt on in the second firing. Two separate furnaces are employed for these distinct operations. The kiln used for baking—Fig. 484FF—has only one chamber, A, and is surrounded by a

Fig. 484FF.

conical brick building, *a a*, termed a *hovel*, that serves at once the purpose of roof and chimney. The construction is nearly the same as that of an upright reverberatory furnace, differing from the porcelain kiln by a better arrangement for the distribution of the flame, and the use of coal for firing in place of wood. The draught is regulated by the aperture, *b*, and passes into the furnace in a downward course, carrying with it the flames in a horizontal direction; *c* is the opening for removing the clinders, and *d* that by which fuel is introduced into the furnace. The flame, before entering the chamber of the furnace, is divided; part of it retaining its original direction, passes through channels below the sole of the furnace, along the horizontal flues, *e*, and enters at the central point, *f*, the remainder circulating upwards through the small chimneys or bags, *g*, situated against the wall, *m*, of the kiln, *A*. Each fire, of which there are six or eight, has a corresponding chimney, *g' g'*, and horizontal flues converging towards *f*, and becoming narrower as they approach the centre. The flame finally escapes through the openings, *h h h*, in the dome of the chamber, *A*, and out of the top of the hovel, *B*. The small openings, *n n*, are for the removal of the *watches* from the seggars placed opposite, and by which the potter ascertains the state of the kiln. The height of the chamber, *A*, averages about eighteen feet, the diameter about sixteen feet.

It being generally the custom, in the manufacture of fine earthenware, to prepare several kinds of goods

at the same time, care is taken in the firing to place those wares, such as ironstone china, *et cetera*, that require the greatest amount of heat, in the hottest portion of the kiln. As has already been stated, no kind of earthenware can withstand the direct action of the flame, especially that from a coal fire; the wares are, therefore, always inclosed in seggars, while the comparatively low temperature at which the wares are baked admits of a great economy of space, the individual pieces being packed closely. The seggars are

arranged in the kiln in columns or bungs after the manner described under *Porcelain*. The temperature of the biscuit kiln ranges from 90° to 100° Wedgwood. The following tabular statements will show the approximate number of bungs and seggars contained in the biscuit kilns at each firing. It must, however, be observed, that the bracket mentioned in the table is not general throughout the Staffordshire Potteries, but has been successfully used for many years by Messrs. COPELAND in their kilns:—

No. 1.—LARGE OVEN—Dimensions, 18 feet diameter; 17 feet 6 inches high.

Number of bungs,		103		Number of seggars,		2414	

The mode of constructing the *seggars* for firing the fine earthenware is shown at Fig. 484gg. The marl, after beating out by the bat, *a*, upon the iron or stone slab, *b*, is cut to the required height of the seggar, and wrapped round the wooden drum or shape, *c*; the necessary thickness of clay to form the bottom of the seggar having previously been placed on the wooden shoard, upon the whirler, *d*, the workman now unites

the edges of the sides together by moisture and subsequent kneading of the fingers; the bottom mass is also trimmed round, and luted up into the side in the same manner, the operation being assisted by the rotatory motion imparted by the left hand to the whirler, *d*. The seggar, after the withdrawal of the drum, is shown at *e*, and the drum at *f*. The composition forming the mass of the seggars is as follows:—

Various grey and black marls from the coal-beds mixed together with the addition of from twenty to twenty-five per cent. of coarsely-crushed old biscuit

seggars, these proportions depending upon the plasticity or porousness of the marls used.

In firing earthenware, that quality of coal is selected

Fig. 484hr.

which produces a long flame, and is not of a caking character. The heat is moderated at first until the furnace and its contents have gradually been raised to a red heat; the temperature is then increased, the draught entering from below, and regulated by the opening or closing of the lid. The state of the biscuit is ascertained by the introduction of hollow balls of red clay, bored through on two sides, to enable their removal from the kiln—the degree of color produced affording a clue to the state of the furnace. These balls or watches become first pale-red, and after passing through several tints become red-brown; at which stage those varieties of earthenware equal in quality, or nearly allied to *iron-stone* ware, are sufficiently fired. The softer varieties are fired when the tests appear slightly tinged with dark-red. The firing in the biscuit kiln occupies about forty to forty-eight hours, the average amount of coal consumed varying from fourteen to eighteen tons, according to the size of the kiln.

The kilns employed for the after-operation of glazing are of the same construction, but somewhat smaller than the biscuit kiln; the temperature of the furnace for burning the glaze being ascertained by the introduction of balls of clay, previously coated with glaze, into the chamber, and which assume progressively the same changes of color with the heat of the furnace. Frequently the trials from the most successful bakings are preserved in order to use them for the purposes of comparison in future operations of the same kind.

Flat pieces, such as plates, *et cetera*, are separated from each other in the seggars by small pointed supports or rests, made of hard baked clay or earthenware, called *cockspurs*, *stilts*, *triangles*, *et cetera*, as shown in Fig. 484ii; those as *a a*, *b b* being fixed into separate holes made in the side of the seggars, the plate resting upon the edges of the prominent portion, rim downwards, or, as is the case with hollow

wares, separated one from the other by the triangle *c* or *d*.

The extent and importance to which the earthenware and pottery manufactures of England have risen,

Fig. 484ii.

can only be estimated by taking the approximate returns of material used and goods manufactured over a given time, in one of the principal localities—such as the Staffordshire potteries—and which may be taken as follows:—

The total quantity of *potters' material*—such as Cornish stone, flint, kaolin, china clay, pool clay, felspar, *et cetera*—used in the various departments of manufacture in the Staffordshire potteries, during the year 1859, is estimated at not less than two hundred and twenty thousand tons; the manufactured ware sent out of the district during the same period, reaching over one hundred and ten thousand tons, which, taken at an average value of twenty-five pounds per ton, will give the enormous sum of two millions five hundred thousand pounds sterling.

Glaze.—In the composition of the glaze the following substances are used in greater or less proportions:—Felspar or Cornish-stone, flint, sand, borax, soda, tincal, boracic acid, crystal glass, minium, litharge, white lead, borate of lime, china clay, carbonate of lime, smalt; the proportions of which differ considerably, partly on account of the variable nature of the body, and partly according to the requirements of the ware, whether white, printed, or painted. The *glaze* is, however, always white, and contains lead, alumina, and soda. Minium and the preparations of lead exert a softening action, while the oxide of cobalt, used in very small proportions, rarely exceeding one-thousandth part, is for the purpose of imparting a delicate blue tinge to the glaze, and counteracting the yellow color of the body of the ware. The essentials of a good glaze are transparency, absence of color, sufficient hardness to resist abrasion, and the property of expanding by heat in nearly the same ratio as that of the body of the ware. The various ingredients are mostly fused together or fritted, and afterwards ground, sieved, and purified, as described, to free the slip from iron to form the glaze. When melted with borax or boracic acid and soda, it is a perfectly transparent green color; with tincal it is impure in color, and of a dirty-brown. The preparations of lead do not always enter into the composition of the frit, but are added to the glaze in the grinding process, with the stain also finely ground. These materials being formed into a thin water fluid, the process of glazing is the same as that described under *Porcelain*. Subjoined are several mixtures for glazes:—

RAW GLAZES.

Common Cream Color Glaze.

Cornish stone.....	150
Flint.....	35
Borax.....	4
White lead.....	300

Rockingham Glaze.

No. 1.

Red lead.....	42
Cornish stone.....	6
Flint.....	4½
China clay.....	4½
Manganese.....	6

Ground finely for use.

No. 2.

White lead.....	60
Cornish stone.....	6
Flint.....	18
Red marl.....	6
Manganese.....	10

Ground finely for use.

No. 3.

Red lead.....	100
Cane marl.....	2
Cornish stone.....	15
Flint.....	20
Manganese.....	15

Ground finely for use.

Yellow or Saffron Glaze.

Underglaze yellow color.....	10 lbs.
White lead.....	20 lbs.

Very finely ground.

Add to which 20 quarts of cream color glaze—4½ lbs. per quart—well sifted together.

VOL. II.

Chrome Green Glaze.

Chrome oxide—green.....	2 lbs.
Flint glaze.....	4 lbs.

Ground for stain.

Add to which 48 quarts of printed glaze—28 oz. per pint—and well sift together.

Dessert Green Glaze.

No. 1.

White lead.....	3 lbs.
Calcined copper.....	3 lbs.
Flint glass.....	1½ lbs.
Flint.....	2 lbs.

Finely ground together. And mix—

Of the above.....	4 quarts.
Printed glaze.....	12 quarts.
Cream color, ditto.....	9 quarts.
Earthenware slip.....	3 pints.

Well lawned together.

No. 2.

Calcined copper.....	10 lbs.
Cobalt calx.....	1 lb.

Ground for color.

White lead.....	23 lbs.
Flint.....	15 lbs.
Blue clay.....	3 lbs.

Ground finely,

And to the above compounds add—

Printed glaze.....	36 quarts.
Cream color glaze.....	36 quarts.

No. 3.

Calcined copper.....	3 quarts.
Ground finely; 29 ounces per pint.	

Cream color glaze.....	20 quarts.
39 ounces per pint.	

Printed glaze.....	10 quarts.
29 ounces per pint.	

Black Glaze.

No. 1.

White lead.....	50
Cornish stone.....	20
Flint.....	10
China clay.....	7
Manganese.....	10

Ground for dipping.

Body as for lustre body.

No. 2.

Red lead.....	25
Cornish stone.....	10
Flint.....	5
Red marl—sifted.....	5
Manganese.....	2

Ground as before.

No. 3.

Cream color glaze.....	20 quarts.
2½ pounds per pint.	

Cobalt blue.....	6 lbs.
------------------	--------

Dark red or lustre body to be used with this glaze.

Royal Blue Glaze.

The same glaze, used upon white body, produces a fine royal blue glaze.

For lighter tints, according to the quantities of stain employed.

FRITTED GLAZES.

Fritted in kiln, and mixed as follows:—

	I.	II.
Cornish stone	150	35
White lead	100	60
Flint	50	30
Frit	300	250

Another glaze as follows:—

Felspar	30	Boracic acid	35
Flint	20	Soda	35
Whiting	20	China clay	15

Fritted in kiln, and mixed as follows:—

White lead	120	Felspar	150
Whiting	40	Frit	60
Flint	60		

To every charge of 600 pounds weight of the above glazes, about three ounces of cobalt blue are mixed to stain, but varied according to the color of the body.

Drab, turquoise, buff, and other fancy bodies, are dipped into glazes such as are here given; or sometimes into mixed glazes, varying between the common and the best.

The furnace for preparing the frit is shown at A—Fig. 484II. *a* is the fireplace, the flames passing over

mass, *f f*, and finally escape over the bridge, *c*, into the chimney, *d*. The frit is withdrawn from the kiln in its molten condition by the opening, *e*, and thrown or run into cold water. This aperture likewise serves for the recharging of the oven, and is closed during firing.

When the dipped biscuit has become sufficiently dry, the glaze is burnt in, being placed in seggars similar to the biscuit seggars, and glazed on the inner surface, to prevent absorption during firing of a portion of the basic ingredients of the glaze, particularly oxide of lead, by which the glaze upon the ware would be rendered rough and deficient in lustre. The pieces are separated from each other by contrivances similar to those already described under *Firing*. The marks caused by the points of contact are easily discernible in the earthenware of commerce. These little inequalities are afterwards removed by females from the ware by sharp steel dressing-tools. The junction of every two seggars in the *bung* is luted with clay to make a perfectly secure mass.

Firing.—The time occupied by the firing of the gloss or glaze kiln is about sixteen hours, and consumes from five to seven tons of coal, according to the size of the kiln, the temperature of which is ascertained by the progressive changes in color assumed by balls of red clay coated with glaze, and introduced for that purpose; but it is usual to preserve these trial balls from the most successful firings for comparison in future operations of the same kind.

Printing.—Although, from the nature of the body, it would be inappropriate to devote the same expense to the decoration of earthenware as to that of porcelain, the former very generally receives ornamentation either with the brush or by printing, and is likewise to a great extent decorated with metallic lustres. The process of printing consists of two parts—first, the production of an impression upon thin paper in a suitable ink, and then transference of the ink upon this paper to the surface of the biscuit. The vehicle which serves as the preparation for embodying the necessary colors, is a composition formed of boiled

Fig. 484II.

the bridge, *b*, into the body of the furnace, *A*, where they are reverberated upon the surface of the fritted

linseed oil, resin, tar, and oil of amber, and which becomes, when mixed with the colors, sufficiently liquid for use by spreading out upon a hot iron plate. In the selection of tints, those only must be chosen which, in chemical properties, are compatible with the character of the glaze, the temperature of the kiln, *et cetera*. Cobalt blue, manganese black, and chromium green, are very common colors, and then various proportions of these, generally incorporated with the ink for the following colors, are here given:—

UNDERGLAZE, PRINTING, AND PAINTING COLORS FOR EARTHENWARE.

Yellow.

Lead and tin ash ..	4 parts.	} Mix well together, and calcine at a gentle heat in a glazing oven; to undergo a second calcination at a higher temperature in the same oven.
Antimony	1 part.	

Orange.

Antimony	3 lbs.	} Calcination as above.
Litharge	3 lbs.	
Lead and tin ash ..	$\frac{1}{2}$ lb.	
Ochre calcined	3 oz.	

Fine Brown.

Chromate of iron	1	} Calcine only once.
Chromate of lead	$\frac{3}{4}$	
Calcined sienna	2	
Oxide of zinc	3	

Brown.

Oxide of manganese ..	4 lbs.	} Well calcined.
Green oxide of chromium	$1\frac{1}{4}$ lbs.	
Cornish stone	4 lbs.	

Yellow Green.

Flint glass	4 lbs.	} Calcined at biscuit oven heat, and well pounded, washed with boiling water until clear, and calcined a second time.
Whiting	$2\frac{1}{2}$ lbs.	
Green oxide of chromium	$1\frac{1}{2}$ lbs.	

Yellow Green.

Green oxide of chromium	3 lbs.	} Calcined together.
Yellow color	3 lbs.	
China clay, burnt at biscuit heat	2 lbs.	
Fine sand	2 lbs.	

Blue Green.

Green oxide of chromium	10	} Calcined together in biscuit oven.
Oxide of cobalt	2	
Flux composed of equal parts of borax and flint	15	

Rose Color Pink.

Oxide of tin	$2\frac{1}{2}$ lbs.	} Calcined in biscuit oven.
Whiting	1 lb.	
Green oxide of chromium	$\frac{1}{2}$ oz.	
Cornish stone	6 oz.	

Purple.

To 15 pounds of rose color pink add 1 pound of cobalt calx and $1\frac{1}{2}$ pounds of fine sand. These proportions may be varied according to tint required.

Black.

Oxide of chromium	6 lbs.	} Calcine in glazing oven.
Calcined manganese ore	9 lbs.	
Cobalt calx	7 lbs.	
Gold litharge	10 lbs.	

Black.

Calcined chromate of iron ..	12	} Calcine together.
Cobalt calx	1	

Blue for flowing.

Black prepared oxide of cobalt	12 lbs.	} Calcine in glazing oven.
Flint glass	4 lbs.	
Oxide of zinc	2 lbs.	

The above for strong color, to be reduced for weaker tints by a flux composed of equal parts of flint glass and flint.

Blue for ordinary printing.

Blue cobalt calx	1 lb.	} Grind for use.
Cornish stone	$1\frac{1}{2}$ lb.	

Or a mixture of half stone and half flint.

May be reduced to 1 part of blue and 5 parts of fluxing material. The fluxing of these blues are much varied by manufacturers.

Of late a manufacture has been introduced of a *flowing blue* and other colors, giving a softness to the coloring upon fine earthenware, which has been much esteemed. This is produced by what is termed a *flow*, introduced into the seggar or fire-case; a few of the *flows* are here given:—

Quick lime	5	} Well mixed together and sprinkled carefully round the bottom edge of the seggar.
Salt	2	
Nitre	$\frac{1}{2}$	
Borax	$\frac{1}{4}$	

Again—

Whiting	4	} Mix and use as above.
Salt	$2\frac{1}{2}$	

Again—

Nitre	4	} Mix and use as above.
Salt	1	
Bone	$1\frac{3}{4}$	
Alum	$1\frac{1}{4}$	

Again—

Quick lime	25	} Mix and use as above.
Chloride of ammonium ..	$2\frac{1}{2}$	
Red lead	5	

These and various other mixtures are introduced for the like purposes.

But the most admired is the *pink color*, obtained from acid stannate of oxide of chromium, with stannate of lime, and very extensively applied to decoration. This pigment, originally a profound secret, has been chemically decomposed by MALAGUTI, from the results of which analysis, a practical mixture has been prepared with great success, more especially at Montereau in France. Analysis gave—

Oxide of tin—Sn O ₂	78.31
Lime	14.91
Silica	3.96
Alumina	0.95
Water	0.61
Oxide of chromium	0.52
Chromate of potassa	0.26
Potassa and loss	0.48

100.00

and from this has been deduced the following mixture:—

Oxide of tin	100
Chalk	34
Oxide of chromium	1 to $1\frac{1}{2}$
Chromate of potassa	3 to 4
Silica	5
Alumina	1

The mixture and preparation of the oil for receiving the colors is as follows :—Mix together—

Old linseed oil	2 gallons
Rape oil	1 quart

To which add—

Red lead	2 ounces
Flowers of sulphur	1 ounce

Place the mixture into an iron cauldron suspended over a clear fire until it begins to boil; the scum which rises is then ignited and burnt off, a close-fitting iron disc covered with flannel being used to extinguish the flames. When the scum is consumed, add gradually two ounces more of red lead, and let the scum be burnt off a second time as it rises. As soon as the oil is sufficiently boiled to become adhesive and stringy to the finger, mix with the mass—

Burgundy pitch	2 pounds
Spirits of tar	1 quart
Gum mastic.....	1 ounce

These ingredients, previously warmed together in a pan, are added very gradually to prevent ebullition, the oil being removed from the fire for that purpose. After the whole has been stirred together for fifteen minutes, it is strained off through a hair sieve and allowed to cool for use. Other oils are sometimes used, but all possess similar powers to the above.

Printed colors are seldom transferred upon the glaze, but are generally printed upon the biscuit, in which case the addition of a flux is not essential, its place being supplied by the glaze.

The process of applying the pattern to the biscuit is as follows :—The design is engraved upon a copper plate in a broad open style, to prevent the lines from running into each other, and forming a blurred appearance. Those portions intended to produce a shaded effect are cut deeper to retain more color. The ink, which is first spread over the surface by a printer's dabber while the plate is on the hot stove, is, after the pattern is well filled in, removed by passing a knife over the surface and wiping with the boss to clean the surface from superfluous oil. The impression is then taken from the plate much after the manner of ordinary copperplate printing, a similar press being employed.

The paper upon which the impression is taken is of a fine, soft, uniform, and durable nature, much about the consistency of tracing paper, and previous to use is saturated with soft soap and well damped. This particular paper is manufactured only in the district under FOURDRINIER's patent. In this manner the various patterns are printed closely upon the paper to economize space, their size being proportionate to that of the ware intended to receive them. After the patterns are separated by scissors, they are placed with the printed side next the ware, and rubbed down upon it with the end of a firmly bound roll of flannel. This is done gently at first, and afterwards more forcibly, until the ink is transferred to the surface of the biscuit. The ware is then plunged into water, when the paper is easily removed after a short time by the gentle application of a sponge. Accurate impressions by this

process can only be obtained when both the surface receiving the transfer and that of the paper bearing the impression are flat. In ordinary manipulations the paper has to be applied to a curved surface with a certain amount of pressure to avoid the creasing, and this, unless carefully performed, is apt to cause a doubling up and distortion of the pattern.

From the circumstance that each differently shaped piece of the same pattern, and each piece of the same shape, but of different size, such as plates, *et cetera*, require a separate engraved copperplate, this becomes a very expensive operation—the process of engraving a set of plates ranging from eighty to one hundred and fifty pounds for the full service, even of the most simple design. This expense is again increased by the unequal wear and tear of the plates, and consequent frequent reproduction of the pattern necessary for a particular piece, such as a plate or saucer, the numbers of which printed, in proportion to other pieces, such as dishes, vegetal covers, *et cetera*, is very large, so much so that often a thousand plates of a pattern are thrown off against one cover or dish.

A very important change in the manipulation as regards the whole process of preparing the designs, regulating the sizes, engraving, and reproducing the plates, has been patented by Mr. WILLIAM MACKENZIE of Glasgow; and the improvements which he proposes are so applicable to the process of decorating clay wares, as regards not only the exactitude and simplicity of the process, but also the economy of production it develops, that ultimately no doubt it will entirely supersede the present expensive system already described. This process may be briefly described as follows :—The intended design is first of all either engraved upon copper or drawn upon stone, of such a size as to fit one of the pieces of the set, say a plate of medium size, and from which an impression in transfer ink is taken, and by a peculiar process transferred to the prepared surface of an elastic sheet. This sheet is afterwards placed on a frame and extended equally in all directions, until the design is accurately brought to the scale required for the plate next in size; while in this extended condition, the pattern is retransferred to the prepared surface of a zinc plate by the ordinary process of lithographic printing. The zinc plate, which has now received the pattern upon the enlarged scale, accurately corresponding in every particular with the original, line for line, is after a little further preparation subjected to the engraving process, *electricity* taking the place of *manual* labor, and in the course of six or eight minutes the plate is finished, presenting all the gradation of depth and tone of the original, only of a different size. The subsequent operation of printing may be greatly simplified, by a chemical preparation of the surface of the zinc, causing a reaction to take place with the oily nature of the ink which then only attacks the engraved parts, and leaves the surface of the plate perfectly free from the ink or grease of the filling-in process. The facility and cheapness with which particular designs can be reproduced, as also the extreme accuracy and uniformity of outline obtainable in repeated patterns, constitute the chief recommendations of this patented process.

After printing, the biscuit cannot immediately be glazed, the oily nature of the mordant or color-vehicle preventing the absorption of the glaze by such portions of the ware as are covered by it. It therefore becomes necessary to destroy this oily consistency by heat before the glaze is applied—a process technically termed *hardening on*. The temperature is raised only sufficiently to burn the oil without producing any chemical action on the color. An oven sometimes employed for this purpose is of the size of a moderate room, quadrangular in shape, and arched above. The room, packed as closely as possible with wares, is luted up, and a small iron box or movable wind furnace, called a *davy*, introduced through a trap in the floor. At the four corners of the chamber, pipes protrude through the roof, and descend nearly to the floor of the room, acting as so many flues to distribute the heat by drawing the flame from the burning cinders to the sides of the chamber. A short pipe is placed in the centre of the roof, the outside aperture of which, furnished with a valve, is connected to those of the four others by levers in such a manner that when the centre one is closed the others are opened, and *vice versa*. After the chamber is fired, this centre valve is kept closed by a rod of lead, the four others being open. The heat from the stove gradually increasing from below upwards, until the temperature of the chamber is raised to the heat at which the leaden rod melts, receives a sudden check by the opening of the centre valve, and the draught being cut off by the closing of the four side valves, the fire is soon extinguished. Other forms of *hardening on* kilns are used for the purpose of destroying the oil; but by such an arrangement as that just described, the most accurate regulation of heat is attained, and at very small expense, the stove consuming the cinders and waste from the baking kilns. The operation of glazing then proceeds in the usual manner.

When the printed pattern is applied to the ware above the glaze, the mordant receives a larger proportion of gum mastic; but where enameling colors are used for the muffle, a *size* is applied to the surface of the glaze, composed of spirits of turpentine, with a small portion of gum mastic dissolved in it; sometimes rosin and sugar of lead being added.

Decoration.—The ornamentation of fine earthenware by the hand and brush is practised only for the production of a certain class of designs, such as flowers, leaves, garlands, dots, *et cetera*, and executed by *artistes* expressly trained for that purpose, and each excelling in a particular branch of ornamentation, such as flowers, foliage, scrolls, and the like.

In the preparation of the several tints used in the higher decorations of porcelain and fine earthenware, great care is required to regulate the exact degree of heat to which the biscuit is raised, with a view to the development of the required tints in the several firings through which the wares pass. The following is the mode of preparation of the various colors and their compounds:—

PREPARATION OF ENGLISH AND FRENCH ENAMEL COLORS FOR PAINTING PORCELAIN AND EARTHENWARE.—*English*.—The beauty and success of the hues in the firing depend in a great measure upon

the purity of the oxides from which they are prepared. They should, therefore, in manipulation always individually represent the same body both in chemical composition and molecular arrangement, so as to be subject to the same changes under similar circumstances. For example, the oxides of iron, chromium, purple of cassius, gold, platinum, *et cetera*, although they may be perfectly pure, are very difficult to work if their precipitation has taken place too rapidly, or at an improper temperature. Under the name of vitrifiable colors are generally classed pigments, without distinguishing between the coloring matter and its base, it being generally supposed that the two substances unite chemically by fusion, and form a homogeneous base; this is only the case, however, in some instances, as, for example, with the oxides of cobalt and the oxides of copper; while in others, on the contrary, as the oxides of chromium, the oxides of iron, *et cetera*, the base is only the vehicle which contains the color, and which serves to fix it upon the surface it is applied to. In considering, therefore, the preparation of the colors properly so called, the *oxides* will be given distinct from the bases or fluxes by which they are fixed upon the surface of the wares.

Oxides.—Amongst the *simple oxides* may be classed—oxide of chromium, oxide of iron, oxide of uranium, oxide of manganese, oxide of zinc, oxide of cobalt, oxide of antimony, oxide of copper, oxide of tin.

Amongst the *oxides mixed with earthy matter*, may be classed chromate of iron, chromate of baryta, chromate of lead, chloride of silver, purple of cassius, umber, sienna, and red and yellow ochres. The mode of preparation of these various materials causes the greatest difference in the quality of the colors into which they severally enter.

Sesquioxide of Chromium—chrome green— Cr_2O_3 —is generally prepared for potters' use by calcining a mixture of equal parts of chromate of potassa and sulphur in a close earthenware crucible at a red heat, the green mass which is produced being well washed to dissolve out the sulphate and sulphide of potassium. The oxide of chromium which remains is further purified by repeated elutriation.

GUIGNET has recently discovered—1859—a new method of preparing oxide of chromium for coloring purposes. A mixture of three parts boracic acid and one part bichromate of potassa is calcined at a temperature of about 932° . An evolution of water and oxygen gas takes place, and there is formed a double borate of sesquioxide of chromium and potassa. This salt, which is stable at the ordinary temperature, is decomposed by water, giving bichromate of potassa and sesquioxide of chromium; the latter in the nascent state combines with water, and forms a hydrated sesquioxide of a remarkably fine color. This is separated from the bichromate of potassa by decantation and washing, leaving a chrome green of a very solid and brilliant description.

Sesquioxide of Iron— FeO .—This is prepared by the calcination of green vitriol, upon the purity of which the brilliancy of the color in a great measure depends. For the calcination a thick cast-iron vessel or earthenware retort is required. During the operation the

sulphate must be kept continually stirred with an iron rod; the powder at first assumes a yellow hue, passing into brown, and finally a greenish brown, which upon cooling changes to red, a sulphuric acid vapor being eliminated during the process, which continues until the powder is reduced about two-thirds of its volume. It is then taken from the fire and allowed to cool, the red deposit being thoroughly washed from all impurities until the water exudes from the filter perfectly tasteless. A red color of a more brilliant tone is obtained from iron by calcining together a mixture of equal parts of sulphate of iron and sulphate of potassa in a crucible slowly up to a dull-red heat. The pigment is afterwards washed with hot water to remove all impurities.

Alum may also be substituted for the sulphate of potassa, or sienna combined with sulphate of potassa may be substituted for the sulphate of iron; but whichever process is adopted, the preparation of the red oxide requires very careful manipulation.

Oxide of Uranium— U_3O_8 —*Uranoso-uranic oxide*—is prepared from pitchblende, which contains from forty to ninety-five per cent. of oxide, and certain proportions of sulphur, selenium, phosphoric acid, lime, magnesia, alumina, silica, manganese, vanadium, arsenic, bismuth, antimony, zinc, tin, lead, iron, cobalt, nickel, copper, and silver. The powdered pitchblende is dissolved in warm nitrohydrochloric acid, and, after all action has ceased, the excess of acid is expelled by evaporation. The residue being heated with a small quantity of hydrochloric acid and water, the solution is filtered from the sulphur and silica, and also from chloride of lead and silver. The arsenic, lead, and copper, with bismuth and tin, are then precipitated from the filtrate by sulphide of hydrogen, and the solution again filtered and boiled, nitric acid being added to convert the protoxide of iron into sesquioxide, which is precipitated by super-saturating the liquid with a large quantity of carbonate of ammonia; this throws down the iron, together with any lime that may be present, and the greater part of the cobalt and zinc oxides, retaining in solution the uranic oxide, together with portions of the cobalt and zinc. The filtrate is then boiled as long as ammonia continues to be evolved, by which means the three metallic oxides, cobalt, zinc, and uranium are precipitated, with the exception of a small quantity of cobalt, which colors the liquid red. The precipitate is collected upon a filter and afterwards washed, dried, and ignited, till its yellow color changes to a blackish-green; it is lastly digested for several hours with cold dilute hydrochloric acid, which dissolves the two compounds of cobalt and zinc, and leaves the pure uranoso-uranic oxide undissolved.

Manganese—Bin oxide of Manganese— MnO_2 .—One of the commonest ores of manganese is found in a state of great purity in Sweden and other parts. The purest variety is that known in commerce under the term of pyrolusite, or black oxide of manganese.

Sesquioxide of Manganese— Mn_2O_3 .—may be obtained by heating pure bin oxide of manganese in a crucible to redness until it ceases to evolve oxygen; or by exposing protonitrate of manganese to a red heat, the sesquioxide remains as a black powder.

Protoxide of Manganese— MnO .—may be economically prepared by heating chloride of manganese to redness with twice its weight of carbonate of soda and a little chloride of ammonium, exhausting the fused mass with water when cold; the residuum is protoxide of manganese.

Oxide of Zinc— ZnO .—is obtained by distilling zinc from clay retorts into chambers through which a current of air is maintained, the volatilized metal burns at the high temperature to which it is exposed, and the oxide is deposited in a series of condensing chambers. The hydrated oxide may be obtained by precipitation from the solutions of the salts of zinc by the addition of an alkali. An excess of the alkaline liquid redissolves the oxide.

Oxide of Cobalt, the ores of which, after grinding and roasting, to drive off as much as possible the excess of arsenic and sulphur, are dissolved in hydrochloric acid, sometimes with the addition of a small quantity of nitric acid. The copper, lead, silver, arsenic, antimony, *et cetera*, are precipitated by sulphide of hydrogen, and to the filtered solution carbonate of lime is added in the form of chalk, by which all the iron, alumina, and a trace of cobalt are thrown down, the nickel and cobalt remaining in solution. To this solution, which must be hot and neutral, a solution of bleaching powder is added in sufficient quantity to precipitate the cobalt, and the menstruum is then well boiled to remove the chlorine as fast as possible. The oxide of nickel is afterwards precipitated from the filtrate by the addition of hydrate of lime, and ebullition.

Oxide of Antimony— SbO_3 .—This is found native as white antimony ore, and may be prepared artificially by boiling pulverized antimony with moderately strong nitric acid, until it is converted into a white powder, which is freed from the excess of acid by repeated washings in boiling water. One part of powdered antimony digested with two parts of aqua-regia and four parts of water, yield 96.6 parts of antimonic oxide. A mixture of seventy-four parts antimony, thirty-nine of nitrate of potassa, and thirty-four of bisulphate of potassa is projected into a red-hot crucible, the ingredients being added rapidly one after another. The resulting mass, after boiling first with pure water, then with water containing a small quantity of sulphuric acid, and afterwards with pure water, will be the antimonic oxide.

Oxides of Copper—red oxide of copper— Cu_2O .—is prepared by heating one hundred parts of blue vitriol with fifty-seven parts of carbonate of soda until the water of crystallization is expelled. The residuum is afterwards mixed with twenty-five parts of copper filings, and the mixture finely stamped into a crucible. It is then exposed to a white heat for about twenty minutes, and after cooling and pulverization, the mass is well washed with water. This process yields about fifty parts of fine colored red oxide of copper.

Black Oxide of Copper— CuO .—The red oxide passes into the protoxide of copper when heated in the air; or it may be conveniently prepared by exposing a mixture of one part of copper filings and two parts of the deliquesced nitrate of copper to the air until the whole is converted into a basic salt, and then igniting

the salt. It communicates a green, and sometimes a blue tint to vitreous compounds; and DAVY has shown that it is the basis of certain colors used by the ancients, which had been supposed to contain cobalt.

Oxide of Tin— SnO_2 —may be prepared by treating the metal with nitric acid. In its most concentrated form the acid does not immediately act, but will violently effervesce with heat upon the addition of a few drops of water. The peroxide of tin remains in the form of a white insoluble powder, and is purified by washing with boiling distilled water, and drying at a dull-red heat.

Chrome Iron Ore— $\text{FeO Cr}_2 \text{O}_3$.—The native chromate of iron is a compound of oxide of chromium with protoxide of iron, but part of the ferrous oxide is replaced by magnesia, and part of the chromic oxide by alumina. By analysis the constituents are as follow:—

Magnesia	7.49
Iron	20.99
Oxide of chromium	59.96
Alumina	11.56
	100.00

Chromate of Baryta— BaO CrO_3 —is prepared by dropping a solution of chromate of potassa into a solution of chloride of barium; the yellow precipitate must be well washed, and is as insoluble in water as the sulphate of baryta.

Dichromate of Lead— $2 \text{ PbO}, \text{CrO}_3$ —*chrome red*—may be obtained by boiling oxide of lead, or its carbonate, with an aqueous solution of monochromate of potassa, or by digesting the neutral chromate of lead in a dilute solution of caustic potassa. LIEBIG prepared it by adding a neutral chromate to fused nitre, and washing the residuum; it is an insoluble, scarlet colored powder.

Chromate of Lead— PbO, CrO_3 —*chrome yellow*.—When chromate of potassa is added to a soluble salt of lead, both solutions being hot, a fine colored anhydrous precipitate is obtained; if the solutions are cold, the precipitate will be pale yellow, and will contain an equivalent of water.

Chloride of Silver— Ag Cl —is best obtained by adding a solution of chloride of sodium in excess to a slightly acidulated solution of nitrate of silver. The curdy precipitate of chloride of silver requires very careful washing.

FLUXES.—General Flux.

Red lead	3	} Fritted together into a perfect glass, and pounded for use.
Borax	2	
Flint	1	

Soft Lead Flux.

Red lead	3	} Ditto.
Flint	1	

White Flux.

Glass	12	} Ditto.
Borax	14	
Flint	9	
Red lead	6	

Chrome Flux.

Red lead	4	} Ditto.
Flint glass	$1\frac{1}{2}$	
Flint	1	

Purple Flux.

Glass	16	} Fritted together into a perfect glass, and pounded for use.
Borax	10	
Lead	9	
Flint	4	

Soft Borax Flux.

Borax	4	} Ditto.
Flint glass	3	
Cornish stone	$\frac{1}{2}$	

COLORS.—White Opaque Enamel.

Flint glass	16	} Run into mass in flinted crucibles or seggars in glazing oven.
Arsenic	$1\frac{1}{2}$	
Nitre	1	
Red lead	$4\frac{1}{2}$	

White Opaque Enamel.

Oxide of tin	1	} Calcined in biscuit oven, and $1\frac{1}{2}$ of calcine added to 2 parts of general flux, and afterwards run down again in glazing oven.
Felspar	$1\frac{1}{2}$	

Yellow.

Under glaze yellow	1
General flux	$2\frac{1}{2}$

Orange.

Under glaze orange	1
General flux	$2\frac{1}{2}$

Red.

Green vitriol calcined to drive off the water of crystallization, and brought to a pale red tint, and then well washed until perfectly free from the sulphuric acid. Here great care is required to obtain the proper tint, neither too pale nor too dark.

Of this calcine take	$1\frac{1}{2}$
General flux	$2\frac{1}{2}$

Chocolate.

Same preparation of vitriol at the heat of a glazing oven, well washed as the foregoing, and fluxed.

Calcine	1
General flux	3

Dark Brown.

Umber	1	} Calcine together in glazing oven, well washed, and to 1 part of calcine add 2 parts of general flux.
Sienna	$\frac{3}{4}$	
Red oxide of iron	1	
Oxide of zinc	$1\frac{1}{2}$	

Another Dark Brown.

Umber	1 part.	} Calcined in glazing kiln.
Calcined terra sienna	$1\frac{1}{2}$ parts.	
Oxide of iron	1 part.	
Oxide of zinc	$1\frac{1}{2}$ parts.	

To one part of the calx add three parts of general flux. Ground for use.

French Yellow Brown.

Oxide of tin	$2\frac{1}{2}$ lbs.	} Calcine in kiln, and to 1 part of calcine add $2\frac{1}{2}$ parts of general flux.
Oxide of zinc	2 lbs.	
Red oxide of iron	$1\frac{3}{4}$ lbs.	

Another Yellow Brown.

Oxide of tin	3 parts.	} In glazing kiln.
Oxide of zinc	2 parts.	
Oxide of iron	$2\frac{1}{2}$ parts.	

To one part of the above add three parts of general flux.

Base for Copper Green.

Flint glass	12	} Run down in glazing oven.
Red lead	27	
Borax	9	
Flint	6	
Oxide of copper	2	

Black.

Calcined umber	1	} Calcine in kiln, and to every 4 parts add 3 parts of general flux.
Blue cobalt calx	1	
Flint glass	1½	
Red lead	1½	
Borax	1½	
Flint	1	

Another Black.

Black oxide of cobalt	2½
Turkey umber	1½
Soft borax flux	2½

Another Black.

Black oxide of copper	1 part.	} Calcined in glazing oven.
Oxide of cobalt	1 part.	
Oxide of manganese	1 part.	
White flux	10 parts.	

To four parts of the above add one and a half parts of white flux.

White Enamel.

Flint glass	20	} Run down in glazing kiln.
Red lead	5	
Nitre	1½	
Arsenic	1½	

Sometimes an addition of the oxide of tin.

Blue Green.

Base as above	10 parts.
White enamel	1½ parts.

Yellow Green.

Base	10 parts.	} Run down.
Enamel yellow	15 parts.	
White enamel	1½ parts.	

Chocolate Brown.

Crocus mentis	4 parts.	} Run at gentle heat.
General flux	12 parts.	

Deep Blue.

Flint glass	4 parts.	} Run in glazing kiln.
Red lead	1½ parts.	
Pearlash	1-16th part.	
Muriate of soda	1-16th part.	
Carbonate of cobalt	½ part.	
White enamel	½ part.	

Mat Blue.

Carbonate of cobalt	2 parts.	} Run in glazing kiln.
Oxide of zinc	2 parts.	
Borax flux	4 parts.	

To two parts of the above add one part of borax flux.

Run down at a gentle heat.

Rich Chrome Red.

Red lead	3 parts.	} Run down at a gentle heat.
Chromate of lead	1 part.	
Chrome flux	2 parts.	

Green from Oxide of Chrome.

Oxide of chrome green	3 parts.	} Calcined at high heat, and well washed.
Carbonate of cobalt	1 part.	
Felspar	2 parts.	

To one part of the above add four parts of soft borax flux.

Run down.

Various tints of green obtained by the addition of enamel yellow, previously given.

 Flux, No. 2 72 }

Various tints of green are produced from the oxide of chrome, with the addition of yellow as given.

Carmine, purple, and rose colors are from the purple of cassius, prepared by precipitating gold from the solution of aqua-regia by nitromuriate of tin; to which precipitate is added a small proportion of chloride of silver, and the flux—No. 3 for carmine, or No. 4 for purple—in proportion, according to the heat required in the process of firing, to produce a fine tint.

Purple of Cassius.

The acids used for the solution of gold for this process are, hydrochloric 1·13, and nitrous 1·41—three parts of the former to one part of the latter. Ten pennyweights of the above aqua-regia will dissolve one pennyweight of fine yellow gold. For the solution of tin, twenty pennyweights of hydrochloric acid, ten pennyweights of nitrous acid, and twenty pennyweights of pure water, dissolve in these quantities ten pennyweights of well granulated tin. The tin must be added by small pieces, each being allowed time to dissolve before more is added, and so on to saturation, when the solution, if properly performed, should assume the clear and bright color of brandy. Great care is required for the performance of these processes.

Many other forms are given by various authors, each preferring their particular methods. The solutions here described having been prepared, the processes will be now given.

Into a vessel of sufficient dimensions pour two quarts of good pure water, into which the solution of gold is to be poured, when it will, in its diluted form, assume a pale straw color; into this the solution of tin is to be carefully added, and stirred continuously with a glass spatula until the cassius is well formed, and the precipitate should be of a brilliant carmine tint. Time having been allowed for the cassius to subside, the water is to be carefully removed by a syphon, and washing continued, by changes of the water, until the cassius is perfectly free from the acids. The cassius must then be carefully collected on a filter, and, whilst in a moist state, is ready for further use.

Rose Color.

The cassius, with fifteen grains of silver and sixteen ounces of flux.

Flux.

Flint glass 4 parts.
 Borax 2 parts.
 Red lead..... 2 parts.
 Flint 1 part.

VOL. II.

To form the Cassius for Purple Color.

Gold solution 10 pennyweights.
 Tin solution 20 pennyweights.

The Cassius with

Silver..... 10 grains.
 Flux 6 ounces.

Purple flux is already given.

Fine earthenware, although chiefly confined to the potteries in Staffordshire, is also made in considerable quantities abroad—in France, in the neighborhood of Paris, at Bordeaux, Saargemünd, *et cetera*; in Germany, at Mettlach, near Saarbrück, and Poppelsdorf, near Bonn. Earthenware is also made at Baireuth, Aschaffenburg, Kelsterbach, *et cetera*, and at Carlsbad in Bohemia; at all of which places several kinds are produced simultaneously with the fine earthenware. The differences in the manufacture are confined chiefly to the manner of preparation of the clay, the composition of the glaze, and the ornamental decoration. At Mettlach four varieties are manufactured.

1. *Stoneware*, composed of plastic clay from the Palatinate, ground quartz from Oberwald or Berncastle, calcareous tufa from Sierk. The glaze contains lead, and the ware has a yellow tint.

2. *Yellow or Nankin-colored earthenware*, composed of grey plastic clay from Vallendar, near Coblenz, and clay from Eifel, which burns yellow. The glaze contains lead.

3. *Hard Stoneware*, containing plastic clay from the Palatinate, and ground quartz and gypsum from Luxemburg. The glaze a tolerably hard lead glass, containing boracic acid.

4. *Porcelain Stoneware*, containing plastic clay from the Palatinate and from Vallendar, with ground quartz and bone ashes. The glaze free from lead, and composed of borax, alkali, and felspar.

Amongst the varieties of fine earthenware may be classed the peculiar manufacture of *clay pipes*. The clay used in the construction of these requires extreme plasticity, together with a certain amount of porosity upon firing. The plasticity found in the layers forming the basis of the clay deposit, is used without the addition of a flux, but to insure the perfect uniformity and pliability of the mass, great care is taken with the kneading and slapping processes.

The manufacture of tobacco pipes, in consequence of the immense demand for them, is one of considerable importance in the potter's art. From a prepared lump of the clay the moulder separates a number of pieces, each sufficient for the construction of a pipe, and rolls them out on a table two at a time, one in each hand, to nearly the form and dimen-

Fig. 484kk.

sions of the intended pipe, the thinner portion having rather more than the thickness of the future tube, whilst the bulbous portion at the end is somewhat less in diameter than the bowl. When these rolls have become sufficiently hardened by exposure to the air, a second workman receives them in bundles for the operation of boring the tube by means of an oiled wire mounted in a wooden handle. With his left hand he forces forward the oiled wire, whilst the thumb and forefinger support the roll, and with a kind of feeling motion guides the point of the wire very accurately along the axis of the roll. The point of the wire is rounded like a button to facilitate the operation, which is performed with surprising celerity.

The whole length of the pipe is not pierced at once, an inch being left unbored, and the unfinished pipe with the wire is placed in the half of the copper mould, *a*, *b*—Fig. 484KK—previously brushed with oil to give smoothness to the stem upon removal. The two halves of the mould, closed accurately together by means of pins, are then placed in a frame—Fig. 484LL—and the edges kept in contact by the screw vice, *a*.

Fig. 484LL.

The stem is thus shaped in the mould, together with any impress or name that may have been cut upon it. The bowl of the pipe is first roughly formed by the introduction of the finger, and afterwards completed by the insertion of the plug, *b*, into the mould. Upon opening the mould the operation of boring is completed, the small pellet of clay which precedes the wire being removed by a little hook attached to the handle of the knife used for forming the edges and bowl of the pipe, which is done by removing the superfluous clay. Finally, the rim of the bowl is formed by the small copper mould, *c*. When the pipes have been removed from the moulds, and the wires drawn out, any ornamentalions not given by the pipe mould are added by means of roulettes and stamps. The pipes are then laid out to dry, the sutures removed with a sharp knife, and polished by grooved agates. When the stem of the pipe is required to be curved instead of straight, the two extremities only are supported upon the drying boards, causing the centre to sink down. The number of complete pipes produced by a good moulder will average five hundred a day, notwithstanding the number of operations each pipe has to undergo.

The white color of the pipe being an essential requisite, requires that they be fired in seggars. When the pipes are short, and there is little risk of fracture or bending, as many as possible are placed in the seggar without reference to any particular arrangement;

but for firing long pipes, ring-formed projections upon which the bowls of the pipes rest, are made on the inside of the seggars, a grooved column in the centre supporting the ends of the stems, which, when projecting above the seggar are protected by a conical lid. In London the clay-pipes noted for elegance of form are fired in a close kiln—Fig. 484MM—shown in section, and from which the flame and smoke of the fire are totally excluded. The bottom and sides of

Fig. 484MM.

the kiln are constructed of similar material with the pipes themselves, the refuse and fragments of old pipes being worked up for this purpose. This close kiln, *a*, is supported over the fire-place, *b*, by the brackets, *e*, a space of several inches being left between the sides of the kiln and the outer casing of the fire-brick, *c*, and the whole inclosed by the *hovel* of brickwork, *d*. The flame circulates freely in the intermediate space between the kiln and casing, *c*, supports being introduced at intervals to keep the kiln in its proper position, and which, being connected together by occasional apertures, serve at the same time the purposes of flues to regulate the direction of the flame. The opening, *f*, in the lining of the kiln, *c*, for the introduction and removal of the pipes, is closed during firing by an iron door luted with clay. The corresponding opening in the kiln itself is plastered

up after charging with clay and broken fragments of pipes. The pipes are supported in the kiln by rings of clay, *g g*, surrounding the sides and the central bearings, *m m*, the weight of the whole charge being distributed between the sides of the kiln and the central column, so as not to bear upon the lowest layer of pipes. These kilns vary in size, and sometimes fire a hundred gross of pipes at once. The firing lasts from ten to fourteen hours, the temperature being gradually raised to the full intensity required for baking. The fuel used is coke, and a small opening, *r*, is left in front of the kiln to enable the workman to judge of the interior temperature.

The porosity of the biscuit causes the burnt pipes to absorb water with avidity, and to adhere in a very unpleasant manner to the lips. The ends of the stems are therefore either rubbed with a mixture composed of gum, soap, and wax, or coated with resin or shellac. Sometimes they are glazed by dipping into a very fusible lead glaze; the covered ends being afterwards exposed to the flame of the furnace for about ten minutes.

Common Earthenware or *Delftware* is characterized by its extreme opacity, its open porous structure, and soft texture; in fracture it is earthy, and always colored, while, instead of a transparent glaze, it is coated with enamel.

In the composition of the mass, certain proportions of potter's and plastic clay, clay marl, and quartz or sand, will always be found—these constituents varying in their nature according to the different localities in which they occur. Thus Paris earthenware consists of—

Plastic clay from Arcueil,	8
Greenish clay marl,	36
White calcareous marl,	28
Yellowish marly sand,	28
	100

Still the various combinations always contain a mean proportion of clay, silica, and carbonate of lime, as will be seen by the following analyses of earthenwares from various localities:—

Description of earthenware.	Silica.	Alumina.	Lime.	Magnesia.	Oxide of iron.	Carbonic acid and loss.	Remarks.
Italian, from Lucca della Robbia,	49·65	15·50	22·40	0·17	3·70	8·58	All effervesce with acids.
Majolica,	48·00	17·50	20·12	1·17	3·75	9·46	
Old Spanish,	46·04	18·45	17·64	0·87	3·04	13·96	
Manasses, near Valencia,	54·71	18·80	19·69	trace	2·20	4·60	
Delft,	49·07	16·19	18·01	0·82	2·82	13·09	
Persian,	48·54	12·05	19·25	0·30	3·14	16·72	
From Rouen,	47·96	15·02	20·24	0·44	4·07	12·27	
From Nevers,	56·49	19·22	14·96	0·71	2·12	6·50	
From Paris,	61·50	12·99	16·24	0·15	3·01	6·10	

The mean of these proportions corresponds nearly with equal parts of silica, pipe-clay, and carbonate of lime. These analyses likewise show that the greater portion of the carbonate of lime has been decomposed by the silica during firing, the amount of carbonic acid contained in the vessels being far too small a quantity to combine with the whole of the lime. All kinds of delftware melt and swell at a high temperature into the form of a dark-brown or green glass, without becoming translucent. The liability to crack, when exposed to sudden variations of temperature, is likewise increased by the large amount of marl in the mass. A corresponding increase of pure clay diminishes the risk.

All the ingredients for delftware are suspended in water, and mixed in the slip state; the mass being brought to the proper degree of consistency for working by evaporation in slip kilns. The operation of forming or moulding upon the throwing-wheel is one of extreme rapidity from the great plasticity of the mass; the finishing processes being afterwards performed upon the lathe. Sometimes plaster moulds are employed; but, in every case, the processes are the same as those already described.

Firing.—Delft earthenware, like fine earthenware, is fired twice; the first baking producing the *biscuit*, which, after receiving the glaze, is fired the second time. Both these operations are carried on in similar kinds of kilns, which are generally upright reverberatory furnaces heated by one or more fire-places, after the manner of those already described. In the firing, the wares of better quality are protected from the flame by inclosure in seggars, while the commoner kinds receive

support in the kiln by clay slabs specially prepared for this purpose, and arranged in separate layers or floors, between which the wares are placed so as to afford free circulation to the flame. The pieces are separated from each other in the seggars by triangles and pegs, as already described. The first firing lasts from fifteen to sixteen hours, and the second for burning on the glaze from twelve to fourteen hours.

The temperature of the kiln averages about 27° Wedgwood. The mass shrinks in the baking from ten to twelve, fourteen, or even fifteen per cent. according to its composition.

The analysis of common delft earthenware is as follows:—

Alumina and sesquioxide of iron,	68·55
Silica,	29·13
Lime,	1·24
	98·82
Specific gravity,	2·363

The glaze or enamel is composed of quartz-sand, soda, common salt, and a mixture of calcined tin and lead. The two metals are more easily oxidized when mixed; the oxide of tin produced— Sn O_2 —acting the part of an acid to the oxide of lead— PbO . The mixture is prepared by placing the lead with about one-fourth of tin in a special furnace, where it is exposed to heat and a current of air. A yellowish ash of tin and lead is formed, which is carefully calcined to oxidize thoroughly all the metallic particles. This metallic ash is mixed to form the enamel in the following proportions:—

No. 1.	
Lead and tin ash, . . .	100 parts.
Sand,	100 parts.
Salt,	15 parts.
Red lead,	5 parts.

{ All sand for opaque glazes should be fritted with soda as follows:—150 sand to 100 soda.

No. 2.	
Lead and tin ash, . . .	32 parts.
Soda,	9 parts.
Salt,	5 parts.
Cornish stone,	25 parts.

{ Fritted together, with the addition afterwards of 50 pounds of white lead.

No. 3.	
Calcined sand,	100 lbs.
Soda,	50 lbs.
Tin ashes,	25 lbs.

{ Fritted together, with the addition afterwards of 100 pounds of white lead.

No. 4.	
Best earthenware glaze,	10 quarts.
Oxide of tin,	40 oz.
White lead,	60 oz.

The larger the proportions of tin in the ash the harder the enamel produced, and *vice versa*. The frit, ground and mixed with water, is applied to the wares in the usual way.

Majolica ware—the revival of which in this country is due to Messrs. MINTON, under the direction of M. ARNOUX. The body consists of a soft calcareous clay, or common delftware body, gently fired and covered with an opaque enamel composed of sand, lead, and tin, forming an excellent surface, upon which the decorations in color are afterwards painted by hand in the various preparations and fired into the glaze. Very elegant cisterns, vases, flower stands, *et cetera*, are now produced in this ware; it is also applicable for the production of friezes and other architectural ornaments. It likewise affords a cheap material for enamel painting, the brightness of tints attained being equal to that produced upon copper. The mode of production may be thus described:—The ware, after formation in the usual manner, is twice fired, first for the biscuit, and afterwards to receive the enamel or basis for receiving the color. In this state it is taken to the decorator, who with his brush paints on the several pigments prepared for the purpose, the ground color being only laid upon such portions as are to be covered, and the several ornamentations added in the same way, each only receiving its particular tint. Great care and nicety are required in this manipulation to prevent the unequal blending of the colors at the edges. Sometimes a shaded effect is given to the ground or ornamentation by the running of the colors into the hollows of the pattern, causing in the firing a greater depth of tone. At other times color is laid over the first ground, and a pleasing blended effect is produced by the running together of the enamels in firing. After the decoration is completed in this manner, the piece is taken to the *muffle*, where the colors are all burnt or fired into the glaze, giving that rich solidity of tone and lustre so peculiar to majolica ware. The proportions for the enamel are here given:—

ENAMEL GLAZING FOR MAJOLICA WARE.

No. 1.	
Lead,	77
Tin,	23

Calcine together, and take—

12

Calcine,	44 parts.
Sand,	44 parts.
Red lead,	2 parts.
Salt,	8 parts.
Soda,	8 parts.

No. 2.	
Lead,	82
Tin,	18

Calcine, and take—

Calcine,	47 parts.
Sand,	47 parts.
Salt,	3 parts.
Soda,	3 parts.

No. 3.	
Lead,	77
Tin,	23

Calcine together, and take—

Calcine,	45 parts.
Sand,	45 parts.
Red lead,	2 parts.
Salt,	5 parts.
Soda,	3 parts.

No. 4.	
Lead,	82
Tin,	18

Calcine together, and take—

Calcine,	45 parts.
Sand,	45 parts.
Salt,	7 parts.
Soda,	3 parts.

All these compounds are fused together, and sometimes yield a blackish mass; but when ground and applied to the wares, they appear as a white enamel glazing.

The following are the colors applied to them:—

Yellow.

White enamel glazing,	91 parts.
Oxide of antimony,	9 parts.

Blue.

White enamel glazing,	95 parts.
Cobalt calx,	5 parts.

Green.

White enamel glazing,	95 parts.
Oxide of copper,	5 parts.

Yellow Green.

White enamel glazing,	94 parts.
Oxide of copper,	4 parts.
Naples yellow,	2 parts.

Violet.

White enamel glazing,	96 parts.
Peroxide of manganese,	4 parts.

Other colors are merely modifications of these, with other compounds.

The white glazing of some of the modern majolica is composed of felspar, borax, and the oxide of tin. This glazing, as well as the colors, is frequently applied directly to the biscuit ware, which considerably reduces the labor of ornamentation, without detracting from the beauty of the manufacture.

ORDINARY POTTERY, such as is now everywhere produced, is intended to afford the less wealthy classes cheap utensils, that are *impervious to liquids*, and which at the same time will *bear changes of temperature*, so as to admit of general domestic use. Ordinary pottery is made in almost every locality, and therefore, of necessity, from very different kinds of clay. Its

extreme cheapness obliges the use of those clays that can be obtained at least expense, such as potter's clay, marl, *et cetera*, and the application of the most ordinary methods of moulding and firing. From the circumstance that ordinary pottery is generally manufactured by a class of persons without the means and opportunities of introducing improvements, the advance of the manufacture is slow; the waste of fuel in badly constructed kilns is frequently a source of great loss, while many of the clays worked into the mass will not withstand a sufficiently high temperature. Ordinary pottery is, therefore, always fired at a comparatively low heat, which renders the mass porous and of low density, and necessitates the use of a glaze. As the temperature required to burn on this glaze must be lower than that which would cause the fusion of the ware, it is generally a lead glaze, and of a very fusible nature. This glaze is always transparent, no attempt being made to conceal the body of the ware, which is generally of a dirty-red, yellowish-brown, or greyish color. The glaze may either be colored or not, the rude paintings with which ordinary potters' ware is sometimes decorated being produced by glazes of different colors, the one forming the ground and the other the ornamentation. In general, a very low style of art pervades the tone of this class of clay wares, though occasionally exceptions are met with, such as the wares produced at Marburg, where the brown colored vessels are neatly ornamented with floral designs, that appear to advantage through the light yellow glaze.

In the preparation of the mass two operations only are required—one, the mixing the clay with the necessary amount of water to bring it to the proper consistency, and during which operation the clay is frequently stirred and turned over to render the action of the water uniform; the other, after evaporation, is the working the mass into lumps, and the removal of all knots, stones, *et cetera*, by the aid of the wire, as already described under *Earthenware*. Clay, when of good quality, is easily worked upon the throwing wheel, and does not shrink so much in the kiln as to cause cracks, besides possessing the qualification of carrying the glaze. These properties, which cannot be previously determined, are all matters of experience, different clays being frequently mixed together for that object, with the addition of sand to diminish contraction when the clay is too fat.

The glaze in use upon ordinary potters' ware is an aluminous lead glass prepared from litharge or galena, which in the firing forms oxide of lead and lead salts, the former combining with the silica.

The substances containing the lead are finely ground and mixed in proper proportions with loam, or if a transparent colorless glaze, with sand. When color is required, metallic oxides are used as pigments—oxide of copper for *green*; manganese for *brown* and *black*; zaffre for *blue*; red antimony ore for *yellow*; and iron for *red*, *et cetera*.

The glaze is generally applied to the surface of the ware either by coating or sprinkling the moist vessels with the glaze powder, the operation of dipping being in general too expensive for this kind of ware.

The proportions between the oxide of lead and silica in the glaze are very variable, sufficient time being generally allowed in the furnace for the oxide of lead to become fully saturated with silica. That this is the case when the heat of the furnace has been sufficiently intense, is demonstrated by the following results of experiments made on twelve vessels specially marked, and after firing digested for some time in distilled vinegar—

Those *too hard fired* gave no indications of lead.
Those *hard fired* gave no indications of lead.
Those *well fired* gave in some cases only traces of lead.
Those *ill fired* gave in every case indications of lead.

In badly baked ware, therefore, acid liquids upon the *first* application dissolve the oxide of lead which is uncombined, or only in weak combination. The amount of lead so dissolved, however, is very small, and the application of lead glaze to the wares is not attended with any danger to the consumer, notwithstanding the great outcry that was raised against its use as engendering endemical diseases.

Often glazes free from lead are used, especially in Vienna, where the glaze contains—borax, one hundred pounds; felspar, fifty pounds; loam, fifty pounds. In Bavaria the glaze consists of the slag from the smelting furnaces, a transparent mass harder than glass, and which gives sparks when struck with steel; in color it is either bottle-green or light and dark blue passing into green; it is not acted upon by acids. In the analyses made by REINSCH it was found to consist of—

			Oxygen.
Silica,	65.00	...	33.70 in the silica.
Lime,	12.35	...	3.53
Magnesia,	2.56	...	0.99
Potassa,	2.00	...	0.34
Protoxide of iron,	5.00	...	1.50
Alumina,	8.00	...	3.73
Oxide of manganese, ...	4.45	...	1.33
			99.36
			7.37 in the bases MO.
			5.06 in the bases M ₂ O ₃ .

Corresponding very closely with the formula—

Although not identical with bottle glass, it is nearly allied to it. This slag is ground up with water, and applied by pouring it over the ware, previously coated on the outside by immersion with a thin film of loam, to give the red-brown tint. The high temperature required for the fusing of this slag, is one of the chief objections attending its use and general introduction as a glaze.

The *kilns* in which ordinary potters' wares are fired are long, horizontal, reverberatory furnaces with one fire-place, from which the flames traverse the introduction of the ware, the smaller pieces in lengthwise towards the chimney situated at the opposite end, and in which is the aperture for charging the kiln being placed inside those of larger dimensions. As the temperature of the kiln diminishes rapidly towards the chimney, a proper disposition of the wares is necessary, those coated with the more fusible lead glaze being placed where the temperature is lowest. The wares are all exposed to the direct action of the flames, precaution being taken to prevent their adhesion together

in the fusion of the glaze. Further description or illustration of the ordinary potter's kiln is here unnecessary, the wares being frequently fired in the same kilns with stoneware and *bricks*, an account of which will be found under the article *Tiles*.

The application of glaze to common potters' ware is sometimes omitted, as in the case of articles for which rapid absorption or evaporation is necessary, such as water coolers, sugar-moulds, butter-dishes, flower-pots, *et cetera*.

The cooling bottles and vessels used for holding liquids illustrate well the use that is made of the porous nature of unglazed clay. Their cooling properties arise from the permeation of the liquid through the pores of the ware to the exterior surface where, by exposure to the air, it is evaporated with great rapidity, maintaining the interior liquid at a temperature several degrees below that of the surrounding atmosphere. The porosity is sometimes increased by the admixture into the mass of substances which will be destroyed in the kiln, leaving minute pores through the body of the ware; a similar effect is produced by a low temperature of the kiln during firing.

Lustre ware is a class of common pottery which receives upon the glaze, after firing, a very thin, delicate, and brilliant coating of metal, burnt in by a subsequent process in a muffle. The reduction of the metal is effected either by some ingredient in the solution, or by a reducing atmosphere through the action of heat. Sometimes the lustre imparts color to the glaze, as well as the metallic coating, an effect of the extreme tenuity of the coating and partial oxidation of the metal.

This effect is produced in a remarkable manner by the *gold lustre*, which is obtained by precipitating a solution of gold in aqua-regia by means of ammonia, the precipitate, which is fulminating gold, being mixed while moist with essential oil of turpentine. In this state it is applied to the surface of the ware, and fired in the muffle, the lustre being brought out afterwards by friction with linen.

Another preparation for the gold lustre is as follows:—Two pennyweights of gold, dissolved in twenty-five drachms of aqua-regia, with about sixty drops of the solution of tin; the solution being gradually added to six ounces of balsam of sulphur, into which a pint of spirits of turpentine is slowly added, constantly stirring until the whole mass is smooth.

Platinum Steel Lustre is formed from a solution of bichloride of platinum in ammonia, mixed by means of a glass rod with *spirit of tar*, composed of equal parts tar and sulphur, boiled in linseed oil, and filtered. The mixture is spread upon the piece, and fired in the muffle, great attention being paid to the temperature of the kiln. If the platinum solution is too strong, it is reduced by the addition of more spirits of tar, and if too weak, concentrated by evaporation. If the wares come out black from the kiln, friction with cotton restores the proper color.

Silver Lustre, which has a silver white hue, is also obtained from platinum, dissolved in equal parts of muriatic and nitric acid; the saturated solution is poured into boiling water, and a yellow precipitate of

the metal is obtained by pouring this mixture into a warm solution of salammoniac, which, after being well washed with water and dried, is applied in the usual way to the surface of the ware by means of a flat camel-hair pencil; it is then fired, not beyond a red heat, and afterwards burnished with a piece of soft leather.

Lustre Cantharide—the remarkable iridescence of which resembles beetles' wings or Spanish flies—is produced from glass containing a large quantity of lead, and to which is added oxide of bismuth and chloride of silver. The wares after coating with the preparation are placed in the muffle, and when heated to redness, leather or similar substances thrown in, the products from which reduce the surface of the metal and produce brilliant coatings, varying in color from green, red, yellow, blue, *et cetera*.

Iron Lustre is obtained by dissolving iron or steel in muriatic acid, and mixing the solution with spirits of tar. The following may be given for the mixtures forming the body of lustre ware:—

MASS FOR LUSTRE BODIES.

I.

Red or brown clay,.....	20 parts.
Cornish clay,.....	8 parts.
Blue clay,.....	4 parts.
Flint,.....	2 parts.

II.

Red clay,.....	50 parts.
Earthenware body,.....	7½ parts.
Manganese,.....	1 part.
Flint,.....	1 part.

III.

Red clay,.....	80 parts.
Black Egyptian,.....	10 parts.

The lead glaze for lustrous ware is usually made as follows:—

Litharge,.....	60
Felspar,.....	36
Flint,.....	15

or other good cream colored glazes.

TILES AND BRICKS.—In considering the formation of the mass, and the subsequent operations by which it is made to assume the required shape, and the degree of hardness desired in this description of clay wares, a similar arrangement and classification will be adopted to that given under **POTTERY**, properly so called.

Mosaic, Plain, and Encaustic Tiles, from the superior density and vitreous fracture of the mass, together with the presence at times of a glaze, and the amount of skill and taste displayed in their design, are justly entitled to take precedence in this department of manufacture.

Mosaic Pavements and Inlaid Paving-tiles.—The manufacture of the highly decorative pavements of the medieval period has, after the lapse of ages, been revived in the art manufactures of this country by the untiring zeal and industry of the late Mr. HERBERT MINTON, under the direction of Mr. M. D. HOLLINS. The chief difficulty in the production of this manufacture is to obtain different colored clays that shall contract and shrink equally during the processes of drying and firing, and without which property it would

be impossible to produce a perfect tile of variegated colors. It is unnecessary to speak of the state of perfection to which these beautiful tiles are now brought, or their fitness for architectural and ecclesiastical decoration. The fine stone body of which they are composed being highly vitreous, and capable of receiving almost any shade of color, renders them peculiarly adapted for such a purpose. The manufacture is extensively carried on by the Messrs. MINTON. The red clay, composing the body of the encaustic tile, is found at Cobshurst, about four miles from Stoke-upon-Trent, and in manipulation receives a facing of a finer clay, to bear the ornamental or colored design, while the back of the tile has a similar layer pierced with holes, the object of which is to prevent the warping of the tile in the fire. The fine clay, composing the ornamental portion of the tile, contracting more in the kiln than the body, would cause it to bend, unless this tendency were counteracted by the layer of similar material placed at the back. The red clay, or marl, previous to working up, is allowed to *weather* by exposure to the air for about half a year. It is then thrown into the mixing vats, as required, and blunged up well with water; after which the clay slip is strained from all impurities by passing it through fine lawn sieves, and evaporated in the slip kiln to the proper consistency for working; or the mass, if for *dry tiles*, is dried into hard lumps, and afterwards ground between mill stones into fine powder, according to the particular processes for which it is intended.

The clay for the body of the encaustic tiles, after wedging and slapping in the usual manner, is shaped into a block in the form of a cube, or parallelepiped, from which the tilemaker cuts off with a wire square slabs nearly approaching in thickness that of the intended tile. These small slabs now each receive the colored facing of finer clay, which is battled out

Fig. 484nn.

and slapped down on their surface. Each tile thus formed is covered with a piece of felt and put into an iron box press of the required size, where it receives pressure upon a plaster of Paris mould having the pattern cut in relief upon its surface. The soft colored clay face thus receives the design, the indentations of which are afterwards filled up with various colored clays. The name of the maker and a few holes to cause adherence to the cement when fixing the tile and also to assist in withdrawing the moisture in the

drying process, are then stamped upon the back, and it is allowed to harden slightly before the next process of filling takes place. The colored materials in the form of thick slip are now poured over the various parts of the indented pattern so as to completely cover the surface—Fig. 484nn. In about twenty-four hours this colored slip is sufficiently hardened to allow of the superfluous clay being removed; for this purpose the tile is placed upon a small whirler, and the pattern brought out by scraping away the clay down to the face of the tile, the cavities only being filled with the colored mixtures. The tile is now properly finished, the edges squared, and all defects corrected; after which it is dried for a week in a warm room before being removed to the stove where the drying process is completed in a period, occupying from fourteen to twenty-one days, according to circumstances. When thoroughly dry the tiles are packed in seggars and fired in the manner described under *Earthenware*, the duration of the baking averaging about sixty hours. The oven is left to cool for six days, after which the tiles are withdrawn in their finished state. The mass contracts in the firing to the extent of one-eighth in every inch. To produce, therefore, an ordinary six-inch square tile, it is necessary to form the model six inches and five-eighths to allow for this shrinkage.

For the formation of encaustic tiles of a more elaborate pattern, the process is varied from that described, the tile being moulded by hand, instead of receiving pressure under a machine, and it is by this manipulation that all the rich and expensive pavements have been produced. These pavements have been introduced in Osborne House, the residence of her Majesty; and under Sir CHARLES BARRY's direction in the House of Lords and the House of Commons; Cleveland, near Maidenhead, the residence of the Duke of Sutherland; and the mansions of most of the nobility, as well as the Senate House, Washington, and St. George's Hall, Liverpool.

Plain self-colored tiles, such as black, red, chocolate, buff, *et cetera*, and also the *tesserae*, are generally termed *dry tiles*, and made of similar material to the encaustic tiles, but subjected to an entirely different process under a method patented by Mr. PROSSER. The prepared clay, after drying upon the kiln till it is quite hard, is ground between stones and reduced to a fine powder, which is afterwards placed upon gypsum slabs slightly damped, and sifted through fine sieves. In this state the quantity required is placed in a strong steel matrix or mould of the size of the intended tile, the bottom surface of the matrix being ribbed, to give a corresponding impression to the bottom of the tile, and cause its adherence more firmly to the mortar or cement in which it may be afterwards embedded, as well as to distinguish the size of tile by the different diapering. Into this matrix, a steel plate with the pattern of the intended tile upon its surface accurately fits, and is brought down with immense pressure upon the surface of the powdered clay, the pressure applied being so great, that the particles are united into a firm solid slab or tile ready for drying and firing. A thickness of three inches of powder will by this compression form a tile one inch thick, sharp in outline, and with a beautiful

polished surface. It is also found that compressed tiles shrink less in the firing than those made from the plastic mass, the former contracting only one-sixteenth in every inch. Many other articles are likewise manufactured by this compressing process, such as scale plates, table tops, furniture panels, *et cetera*, and also with smaller presses and dies, the tesserae for mosaic work, and ornamental buttons for shirt studs.

The number of tiles produced by a single machine is very large, between fifty and sixty dozen being often turned out in ten hours by the labor of one man, while the number of tesserae produced in the same time is scarcely less than from twenty to twenty-five gross.

The celebrated white-glazed tiles which are now so much appreciated for the walls of bath-rooms, dairies, and other domestic comforts, are largely manufactured by this firm under the same process.

Many other descriptions of vitreous paving tiles are also made, and are in large demand for the more ordinary purposes of architectural embellishment. At Tunstall, near Burslem, at the Tillery Works of Messrs. GARRETT Brothers, great improvements have been effected in the form and appliances into which this material can be worked. Hollow pillar shafting of red clay for churches, ventilating ridge roof tiles, and various other applications might be mentioned, as showing the immense field of constructive art into which this material, under skillful treatment, may be carried. In general, the manufacture of tiles being very similar to that of bricks, many of the operations will be described under that section.

Tiles may be classed under three divisions, paving tiles, roofing tiles, and drain tiles, each of which comprehend numerous other varieties. The great distinction between tiles and bricks arises from the greater thinness of the former, and the consequent necessity of increased purity and tenacity in the mass; greater care is also bestowed upon the processes of their manufacture, tiles being always dried under cover.

Roofing Tiles are of three kinds—pan tiles, which are of a curved shape; plain tiles, flat and of various shapes, often arranged to form elegant patterns when laid upon the roof; and ridge roof tiles, formed to cope the top of the roof, and often highly ornamental.

Drain Tiles belong to the coarsest class of earthenware, and are of various shapes; sometimes curved over a mould, and sometimes formed by forcing the material through a machine by mechanical means. Other articles, likewise, come under this denomination of wares in their manufacture, such as chimney-pots, tubular pipes for water or drains, and which sometimes require the assistance of the lathe to complete their formation.

Processes of Manufacture.—The marls used to form the mass for working are previously weathered and tempered, the period of exposure depending upon the state of the weather; a frosty atmosphere or a warm sun is more conducive to speedy tempering than a succession of wet and dry days. The marls, when in a proper condition, are taken to the crushing mill—Fig. 48400—where, by passing successively between the sets of rollers, *a, b, c*, through a gradually narrowing aperture, the mass becomes thoroughly pulverized, and

in this state is thrown into layers of the various marls, where it is again weathered, and left for a considerable time to mellow or ripen, and sometimes water is added to hasten this process. It is afterwards tempered and

Fig. 48400.

prepared for the moulding processes by passing through the pug mill—see *Earthenware*—from whence it comes oozing out in a mass thoroughly kneaded together and possessing great tenacity. This plastic mass, after separation into blocks or lumps, is conveyed away and stored under cover for future use.

The *moulding* or forming of pantiles is carried on under sheds, the moulding tables being placed on one side, while the remaining space is filled with the *blocks* or drying shelves to receive the pantiles after forming. The prepared clay, after being cut into lumps termed *half pieces*, is brought to the moulding table—Fig. 48400—where the lumps are batted and squared up by an assistant into masses or slabs, *a*, about the size of the mould, and about four inches thick. From this block, by means of a wire, he separates a thin slice the size of a tile, and passes it over to the moulder. The *block* and *stock board*, *b*, for receiving the tile-mould is firmly secured to the moulding table by a strong tenon and mortice; four pegs, *d*, driven into the table at the corners of the block and stock, serve as a support to the mould, *c*, and at the same time regulate the thickness of the tile—five-eighths of an inch. The moulder, having sanded his stock-board and placed his mould on the four pegs, takes the slice of clay from the assistant, and placing it in the mould, smooths the surface with wet hands, and with a brass wire strained upon a wooden bow cuts off the surplus clay level with the mould, and turns the tile out upon the *washing-off frame*, *e*, where it is pressed by the hand into the requisite curved form. It is now struck smartly with the splayer, *f*, and turned over upon that implement for conveyance to the block, where, on withdrawal of the splayer, it is deposited for drying with the convex side uppermost, remaining here for

one or two days. When the tiles are nearly dry they are taken to the *thwacking-frame* or horse, the top of which is curved to correspond with the intended outline

Fig. 484pp.

of the tile, and fitted with a wooden block similarly curved. Six or seven of the tiles are now placed upon this horse, and the workman lifts up the wooden block and gives them two or three smart blows, which corrects any warping that may have taken place during the drying process. The tiles are now carried to the kiln.

Firing.—The tile kiln—Fig. 484qq—as constructed in the neighborhood of London, consists of an oven or chamber, *a*, heated underneath by furnaces, *b*, from which the flames circulate freely through the oven by the flues shown in detail at *c*; the whole is inclosed in the brick hovel, *A A*. The time occupies six days, the fires being lighted on Monday morning, and not put out until Saturday evening. The consumption of coal for each firing is about eight tons, but varies with the nature of the goods to be burnt; hollow goods, such as chimney-pots, garden-pots, *et cetera*, requiring less than the more solid wares. These kilns average seventy-five feet in height to the top of the hovel, with an interior diameter of about thirty-six feet; the oven itself being about fourteen feet square by ten feet high.

In the Staffordshire potteries the kiln is of more moderate dimensions; and the fires not being placed in vaults underneath the body of the kiln, are in general protected from the set of the wind by a wall about six feet high surrounding the kiln, and placed at a convenient distance to allow space for the proper regulation of the fires. After the oven is filled, the doorways are built up with bricks daubed over with street-sweepings or clay as a luting; and the fires, after kindling, are burned slowly for the first five hours, after

which the heat is progressively increased for the next thirty-three hours; the space of thirty-eight hours being in general sufficient for hard fired blue tiles or bricks.

Fig. 484qq.

The temperature of the kiln is determined by the appearance of the mouths and top outlet of the kiln, as well as by trial pieces. When sufficient heat is attained, and before the fires burn hollow, the mouths are banked up with ashes to prevent the passage of cold air through the oven; and the whole is allowed

Fig. 484rr.

to cool gradually for twenty-four hours before the contents are removed. The operation of firing the kiln generally takes place once a week, and consumes from five to six tons of coal and slack. In charging the oven, the floor is first laid with about two thousand bricks placed edgewise in courses one above the other, *a*—Fig. 484rr—the bricks in the first seven courses being so

disposed as to leave a flue from each fire-place of an average width of seven inches, and the top course, *b*, so as to cover this space, and form the flues. Upon this foundation the tiles are placed in bungs of twelve laid alternately cross and lengthwise; the nibs on the tiles spacing them off, and supporting them in a vertical position. Each side of the square is built up with bricks, *d*, allowing sufficient space in the interstices for

the uniform diffusion of heat through all the goods placed in the oven, a desideratum of the greatest importance in the firing of blue bricks and tiles, and for which the circular form of oven is found best adapted.

The following table gives the analyses of the clays used in the Staffordshire potteries, and found in the district, arranged in the order of their *fusibility*, commencing with the most easily-fusible clay:—

ANALYSES OF CLAYS FROM BASFORD AND THE STAFFORDSHIRE POTTERIES.

The colors to which the different clays burn in the kiln are given below, the figures corresponding with those of the above table:—

1. Rotten red marl will not stand heat, but fuses.
2. Seggar marl burns *light buff*—a firebrick.
3. Mixture of clays 5, 6, 7, 8, burns *good blue*.
4. Clay from Stoke-upon-Trent burns *red*.
5. Dun-colored marl burns *good blue*.
6. Top-yellow marl burns *reddish blue*.
7. Red marl burns *blue*.
8. Mingled marl burns *blue of a reddish tinge*.

Ornamental ridge and roofing tiles are in general made by a similar process to that described, greater care being required in the moulding and formation of the piece according to the nature of the design; and if this be very elaborate, the tile is sometimes formed of separate pieces united together after moulding, much in the same manner as described under *Earthenware*.

Of late years considerable ingenuity has been exercised in the invention of machines to supersede hand labor in the production of roofing, agricultural drain tiles, water pipes, *et cetera*, all which machines are constructed upon the principle of forcing the prepared clay from a cylinder through a die-plate fixed at one extremity, which delivers the tiles or tubes in the various forms required. As similar machines for the production of bricks will be noticed under that head, it will be sufficient here to describe the method of producing drain pipes by the hydraulic press, carried on at the manufactory of REICHENECKER, at Ollweiler in Alsace; a process which will at once explain all others of a similar character. The clay mixture to form the pipes, after proper purification, is thoroughly kneaded by passing it between two cylinders revolving at different velocities, which causes them to exert a tearing action upon the mass, the distance between the cylinders being regulated by screws. The mass undergoes a further process, which is necessary before it passes to the moulding apparatus, namely, the expulsion of the minute particles of water retained in the clay by the force of capillary attraction, so powerfully as to resist the action of the press, and which would prevent the

mass from attaining that degree of density necessary to insure its durability and nonabsorbing quality when exposed to constant pressure and the action of liquids.

It is desirable that the mass shall not become too dry, otherwise the process of moulding would be

Fig. 484ss.

rendered difficult; a medium is therefore secured by breaking it up into balls of about eight inches dia-

meter, which are suffered to half dry, and are afterwards repeatedly *slapped* upon a smooth stone to produce a perfectly homogeneous mass. The moulding press—Fig. 484ss—consists of two hollow cast-iron cylinders, A A, fixed near each other on a strong movable frame or cradle, B B, by which means they can be brought alternately under the ram, *a*, of the powerful hydraulic press, *c*, and which is brought into action by the pump, *c*, and supply pipe, *d*. The rods, *e e*, which are attached to the descending beam, *f*, are for the purpose of raising the ram after each operation, the winch, *r*, and pulleys, *f f*, carrying the rope. The conical moulds, *m*, with the mouthpiece, *n*, for the pipes, are attached to the lower extremities of the cylinders, A, and are changed according to the nature of the article to be manufactured. These conical moulds carry the cast-iron mouthpiece, *n*, by the rod, *s*, passing through the centre, and secured into the crosspiece, *g*, cast in one piece with the mould. The plastic mass placed in the cylinder is thus forced by the pressure of the ram through the mouthpiece into the shape of a tube or other article, and is cut by a wire into the requisite lengths, which are removed on a tray to the drying kiln, where they are placed in an upright position upon perforated supports, to avoid as much as possible any bending or want of uniformity in the drying process, a circumstance which would infallibly cause them to split in the kiln. The operation of firing is always one of great risk, as, notwithstanding the care that is taken, the pipes often crack in a longitudinal direction. The application of hydraulic power to the formation of these pipes renders them sufficiently dense and strong to resist a pressure of from thirty-five to forty atmospheres—over one thousand pounds to the square inch—an amount far beyond the capabilities of a pipe manufactured in the ordinary manner. Their diameter varies from one inch to about eight inches, with a proportionate increase in the thickness of the substance. Pipes of a somewhat similar nature, but of larger dimensions, are manufactured by GARRETT Brothers, near Burslem Peake, and others in the locality, at Llwynnenion, North Wales, and also at Lambeth, London.

Bricks or artificial stones are intended to replace natural stone whenever this is not to be had, or the hewing and cutting becomes too expensive. Bricks, therefore, are always formed or moulded at once into the required form, varied according to the purposes for which they are intended, such as wall bricks, arch and rectangular or wedge-shaped bricks. These forms never exceed more than a few inches in thickness, on account of the contraction and difficulties attending the drying of larger masses, and they acquire the requisite solidity by burning in the kiln. From the necessary competition into which artificial bricks enter with natural stone, economy in production is an essential point; they are therefore seldom ornamented, and the color is generally confined to the natural hue assumed by the clay in firing. The preparation and purification of the mass are also extremely simple, and are generally performed upon the *field* where the materials are obtained. Bricks, being thicker and more massive than ordinary potters' ware, are necessarily subject to a much greater contraction, and consequent

liability to crack—a defect which is remedied as much as possible by mixing into the mass cheap noncontractile substances, such as sand, calcareous marl, coal and coke refuse, peat, sawdust, *et cetera*. Sometimes the brick earth contains naturally a sufficient amount of sand or lime, at others the mean quality is obtained by a mixture of clays.

In the neighborhood of London, where bricks are the only material employed for building, the clay is obtained from the alluvial deposits in the London basin that lie above the *London clay*, and consists of layers differing in composition from each other. The lowest deposit containing clay, mixed with fragments of chalk and various gravels, *et cetera*, is rarely used, and passes gradually into the middle stratum termed *malm*, also of clay, but mixed with finer fragments of chalk and sand, in place of the coarse gravel; while in the upper layer the clay preponderates, the gravel and sand being in much smaller quantities, and the proportion of lime is so small that the clay hardly effervesces with acid. This upper stratum is there too fat, and requires to be incorporated with coal cinders or sand, while the middle strata possessing more sand receive only the addition of cinders. Near London and other large towns in England the bricks of the greater number of houses are composed of the earth removed from their foundations. From the uses to which bricks are applied, it is essential that they fulfil certain conditions, as follows:—

Bricks, to be good, must be sufficiently firm and hard to support, without crumbling or giving way, the superincumbent mass they have to sustain, and not be subject to break in carriage.

Bricks must be made so as to withstand pressure, to lie flat upon one another, and have a smooth straight surface free from hollows and cracks.

They must also possess sufficient porosity to admit of a proper degree of adhesion to the mortar, and cause it when dry to form a firm and durable cement.

They must, likewise, possess a hard and uniform structure throughout, so as to afford facility in dressing with the trowel, and not split in contrary directions. They should be able at the same time to withstand changes in temperature, when placed in flues, fire-places, chimneys, *et cetera*, as well as the influences of moisture and frost from external causes.

Some of these necessary qualifications can only be attained by a proper mixture of the mass, and others by attention to the processes of moulding and firing. These varieties of clay are generally incorporated with various substances, such as lime, iron, pyrites, stones, gravel, organic remains, *et cetera*, which, unless removed, are very injurious. Thus when clay containing particles of limestone, chalk, or calcareous petrifications, is formed into bricks, the firing in the kiln converts them into caustic lime, and whenever the water has access to the bricks, and penetrates to these nodules, the slaked lime, expanding, destroys the brick. Iron pyrites is decomposed in the same manner by the fire, and leaves cavities in the mass, giving the brick a greater tendency to fracture in those parts. Vegetal remains, roots, *et cetera*, often occasion the splitting of the bricks dur-

ing firing by the sudden evolution of gas. In the selection and mixture of the clays great care is required; clay, if too *fat*, produces bricks liable to bend and crack in the fire, and with a texture denser and less porous than is required. On the contrary, if the clay is too *poor*, the bricks will be too soft, and easily crumbled to pieces.

The manufacture of bricks may be classified under five heads—*Preparation of Brick-earth, Tempering the Mass, Moulding, Drying, and Firing.*

Preparing the Brick-earth.—The clays, after digging and weathering, as already described under *Tiles*, are classed by the brickmaker into three qualities—*strong clay, mild clay, and malm.* Strong clay in general is sufficiently free from stones to be used for the purposes of brickmaking without washing, but requires that there be mixed with the mass chalk, reduced to the consistency of cream, to counteract the warping and contraction it would otherwise undergo in the process of firing, and to improve the color of the brick. Mild clay has to be passed through the wash-mill, to free it from gravel, and other impurities, before working. The amount of sand present renders it less liable to shrink and warp than the strong clays; but its texture is so loose and incoherent, that a mixture of chalk is necessary to bind the mass together, and to take up the excess of silica in the firing. Malm is an earth suitable for making bricks without any addition, but as it now exists naturally in very limited quantities, recourse is had to the production of an artificial malm by mixing chalk and clay together, previously reduced by passing through the wash-mills. The mixture is run into shallow pits, where, by evaporation and deposit, it becomes of sufficient consistency to be worked up in the subsequent operations. This process, on account of the expense, is only adopted for the best qualities of bricks in the vicinity of London, the mass for commoner kinds being simply mixed together. The object of adding chalk to the clay is twofold—first, mechanical, by diminishing the contraction of the brick; and secondly, chemical, as a flux during the firing, by combining with the silica of the clay. A well-burnt London brick is a silicate of lime and alumina, and differs greatly from an ordinary red fired brick made without lime or alkaline matter, the silica and alumina of the brick earth in this case being only in mechanical, and not in chemical combination. The preparation of the brick earth is much the same process as that described under *Tiles*. In the midland districts the clay is generally ground and crushed between iron rollers, whereas in the vicinity of London the preparation is effected by the wash-mill, and afterwards brought to the proper consistency by evaporation in pits, and *soiled*, or covered with sifted ashes, and left to mellow.

Tempering.—The *tempering* of the mass is performed in various ways, according to the practice of the locality where the bricks are manufactured. The old-fashioned way of tempering by treading consists in spreading out a moderately-thick layer of clay over a wooden floor, and kneading it well over with the naked feet, by which the workman is enabled to detect the presence of stones, roots, *et cetera*; fresh clay and

water are again added, and the operation is repeated until the whole mass becomes so stiff as to impede the action of the feet. Sand, coal-ashes, and similar additions, are sprinkled over the clay and incorporated with the mass, until the whole appears uniformly soft and moist. The extensive demand for brick generally necessitates the employment of machinery, and the *pugging* or *grinding* of the mass takes place in a mill similar to those already described under *Pottery*.

Moulding.—The moulding operation in the manufacture of bricks and tiles is simpler than that of any other kind of clay wares. The workman is supplied with a stock of prepared clay by his side, a small bench or table before him, a tub of water and some dry sand, and an assistant. Two methods of moulding are in use—*slop moulding*, where the mould is dipped in water to prevent adhesion, and *pallet moulding*, where sand is sprinkled over for the same purpose. In *slop moulding* the newly made brick is carried in the mould by the assistant to the *flat* or drying-floor, and whilst this is being done the moulder proceeds with a second mould, the first mould being returned by the time the second brick is ready.

In *pallet moulding* only one mould is used, the brick as it is formed being turned out and placed upon the hackbarrow, and wheeled away to be built into *hacks*, or low walls for drying. The mould is represented in Fig. 484TT; *a* is a four-sided frame of sheet-iron rivetted together at the angles, and strengthened with wood at

Fig. 484TT.

the two sides. The bottom of the mould is detached, and forms what is called the stock-board, *b*, consisting of a piece of wood plated with iron round the upper edge, and filling the mould accurately but easily. Four iron pins, *c c*, are driven into the moulding bench, the stock-board rests upon them, and the thickness of the brick is regulated by their height above the surface. The hollow in the bed of the brick is formed by a piece of wood, *d*, called a *kick*, of the size and shape required, and fastened upon the upper side of the stock-board. The operation of moulding is as follows:—The assistant, or *clot-moulder*, sprinkles the stool with dry sand, and, taking a *clod* or *clot* from the tempered mass, roughly kneads and moulds it into the shape of a brick, and passes it over to the moulder, who having sprinkled sand over the mould, places the clot upon

the stock-board, and dashes the half-formed mass with great force into the sanded mould; the mass which has become flattened by the shock, is forced into the angles of the mould by one or two rapid strokes of his hand; he then, with the *strike*, which has been previously wetted by immersion in the tub, removes the superfluous clay, which is received back by the clot-moulder for reworking. Finally the brick is dexterously turned out of the mould, and conveyed away, while the processes of sanding, *et cetera*, are proceeding quickly for the formation of a second brick.

The number of bricks which a workman can mould in a given time is very great, but depends very much upon the strength and ability of the operator. A moulder with proper assistance will make two thousand bricks in a working day; sometimes a much higher number is attained. The manufacture of the blue facing and paving brick is extensively carried on in Staffordshire; it possesses the same qualities as the blue pipe, ridging, and roofing tiles, and is peculiar to that locality. The annexed tabular statement received from one of the works, and showing the pieces produced there in 1859, will give some idea of the magnitude of the consumption.

STATISTICS OF A BRICK AND TILE MANUFACTORY OF
STAFFORDSHIRE.

Paving quarries,.....	1,000,000
Blue front bricks,.....	150,000
Paving bricks,.....	75,000
Roofing tiles,.....	500,000
Roofing ridges,.....	80,000
Ornamental bricks,.....	150,000
Front red bricks,.....	150,000
Common blue bricks,.....	620,000
Garden edging tiles,.....	25,000
Sanitary tubes,.....	10,000

besides large numbers of other articles not enumerated.

Machinery is sometimes substituted for manual labor in the process of moulding; but from the circumstance of the actual cost of moulding—about one-fourth of a penny for sixteen bricks—bearing so small a proportion to the total cost of brickmaking, it can only be employed with economy in the production of large numbers. The interest of capital, the necessity of keeping a machine constantly at work, and the cost of the motive power which such machines require, demand a very extensive market for the produce. In small brickworks, therefore, machinery effects no actual saving, and is not generally introduced for brick moulding. The mechanical contrivances for producing bricks may be classed under the following denominations:—

1. Machines with actual moulds similar to hand moulds.
2. Machines in which the moulding is performed by several moulds.
3. Machines which cut or stamp out bricks from a cake of clay.
4. Machines which produce a continuous strip or band of clay, and subsequently divide it into separate bricks.

It is unnecessary to enter into the mechanical details or respective merits of these various contrivances; the general principle being easily understood by reference to the machine constructed by Mr. HUNT, and very

generally adopted. A and B—Fig. 484UU—are two cylinders of equal diameter, geared to revolve together, and so placed as to form the front and back of the

Fig. 484UU.

hopper, *a*, the two sides of which are of iron, and arranged to form an opening at the bottom corresponding to the length of a brick, the width being regulated by the distance between the cylinders. When the hopper is filled with tempered clay, the mass forced forward through the opening by the revolution of the cylinders, will have the exact dimensions of a brick. Beneath the hopper, an endless chain, *b*, traverses over the rollers, *c c*, simultaneously with the motion of the cylinders. The pallet-boards, *d d*, are placed at given intervals, to correspond with the thickness of the brick required, and as each pallet-board arrives under the moulded mass, a wire, stretched across a frame, is brought forward and separates the brick, which is at the same time carried onwards by the motion of the endless chain—an operation repeated each time that a pallet-board comes under the hopper.

Drying.—When the bricks placed upon the drying ground in the process of moulding, have become sufficiently firm to be handled without risk of bending, they are set on edge, and piled or *hacked* in the same position until they are six or eight bricks high, spaces being left between them for the free circulation of the air through the dwarf wall thus formed. During the night, or when rain is apprehended, the walls and sides are protected with boards and straw. Sometimes during the process of drying the form of the brick is corrected in any twist by striking with a flat board; a plan that greatly improves the appearance of the brick when price admits of its adoption. Bricks that are intended to be fired in the *clamp*, require to remain in the hacks much longer than those that are fired in a kiln, from the circumstance that the firing in the clamp attains its full heat almost immediately, whereas, on account of the temperature of the kiln being capable of regulation to extreme nicety, the bricks, if *green*, can be dried in the latter by a gradually increasing heat.

An ordinary blue Staffordshire brick, wet from the mould, which weighs twelve pounds four ounces, will

weigh, when fired, only eight pounds one ounce; having lost by evaporation in the drying and burning four pounds three ounces, or thirty-four per cent. of its original weight; the specific gravity being as follows:—

Wet state from mould,	2171
Dry state, ready for kiln,	2075
Fired state,	1861

The loss in weight of a brick by drying and firing will be further illustrated by the following table:—

1859.	Hours of weighing.	Loss in ounces.	Number of hours between each weighing.	Loss of weight in ounces, during each consecutive twelve hours.
July 13.	7 A.M. weighed 196 oz.			
"	11 A.M. " 191½ oz.	4½	4	} 12 hours day, 27½ oz.
"	3 P.M. " 173½ oz.	18½	4	
"	7 P.M. " 169 oz.	4½	4	
July 14.	7 A.M. " 163½ oz.	5½	12	} 12 hours night, 5½ oz.
"	11 A.M. " 157½ oz.	5½	4	
"	3 P.M. " 153½ oz.	4½	4	
"	7 P.M. " 152½ oz.	1½	4	} 12 hours day, 10¾ oz.
July 15.	7 A.M. " 150 oz.	2½	12	

46

Total loss by evaporation in drying, previous to firing in the kiln, being twenty-three and a half per cent. of its original weight, and the further loss in firing amounting to fourteen per cent.

Firing or burning is performed in very many different ways, the nature of the fuel which the brick-maker has at his disposal, together with the cost and custom, being all taken into consideration. It is also considerably influenced by the nature of the work, whether stationary or changing to different places; the prices of labor, carriage, *et cetera*, likewise enter into the calculation. The burning of bricks, however, may generally be classed under two methods:—

1st. A *kiln* specially constructed for the purpose, as in the potteries, is used and charged each time with the bricks or tiles to be fired. Such furnaces may be open, close, horizontal, or vertical.

2nd. The bricks are piled one upon another to form a temporary kind of furnace, with the necessary flues; this arrangement is termed a *clamp*, and is well adapted for burning a large number of bricks at once, but not at all suitable for the finer kinds where a sharp outline is necessary.

Kilns, on the contrary, will burn all kinds of bricks and tiles equally well, but, being somewhat expensive in the construction, are only used under certain circumstances. These kilns are similar to a potter's oven, but without bags, or chimneys, or the exterior hovel, the bricks being so placed in the kiln as to form the flues to regulate the heating. In general they average from ten feet to ten feet six inches in diameter; the consumption of coal is about six tons. This construction of furnace is also modified for the firing of the better kinds of goods as well as of the salt glaze sanitary tubes now so generally used throughout England.

The process of burning in *clamps*, the great simplicity of which has given it the preference for general purposes where the locality is so far removed from any kiln as to render carriage too expensive, takes place in the open air; protection being afforded by movable straw hurdles from the too free circulation of air or wind, which might cause combustion to proceed too rapidly in one direction, and put an end to all control over the fires. The clamp, which will often comprise as many as eight hundred thousand bricks, is coated upon the exterior with loam or burnt bricks, and often occupies from eight to ten days in its construction,

according to the number of layers of bricks. Fig. 484vv represents a transverse section of a clamp; the layers of fuel used in firing the bricks, and consisting of

Fig. 484vv.

cinders and small coal, are shown at *b b b*; *liveholes* or flues filled with faggots, and extending through the whole thickness of the clamp, being left to ignite the layers of *brees*, the flames from which permeate the interstices and escape at the top. The firing of a large clamp is commenced by the successive ignition of the liveholes at one end only, and, when thoroughly lighted, the mouths of the whole are stopped with bricks, and plastered over. The proportion of *brees* for firing every hundred thousand bricks, is generally thirty-five chaldrons sifted ash mixed with brick earth, and twelve chaldrons to light the clamp, averaging a cost of ten shillings for every hundred thousand bricks. If the proportion of *brees* is too small, the bricks will be underburnt, tender, and of a pale color; if too much fuel is used, there is danger of the bricks fusing and running into a kind of slag or *clinker*. The length of time of firing varies from twenty, thirty, to even fifty days, according to the size of the clamp. Bricks situated upon the outside of the clamp, and called *turnovers*, are underburnt and placed upon one side for reburning in a future clamp. Bricks situated near the livehole, and exposed to the full intensity of the fire, will be found fused into *clinkers* or *burrs*. Considerable loss occurs in this particular, the clinkers and adjacent bricks being firmly fused together, and attached to the base of the clamp, from whence they can only be removed with crowbars at considerable cost of labor. The loss by fracture, clinkers, *et cetera*, averages about ten per cent. The different qualities of bricks may be known by their color in the firing, and a very important part of the brickmaker's business

consists in sorting the bricks as they are removed from the kiln or clamp. The hard-baked bricks, generally of a dark greyish-brown, are employed for outside work, the well-baked bricks of a red color for walls, while the half-baked yellowish-red or yellow bricks are used for interior work. The harder that bricks are burnt the more sonorous they become when struck, and *vice versa*; they also last longer when exposed to frost than those which are less burnt.

The several descriptions of brick made for the London market may be classified as follows:—

FIRST QUALITY—MALMS.

Cutters are the softest, and used for gauged arches and other rubbed work.

Malms—Best building bricks, used only in fine brickwork; color, yellow.

Seconds—Sorted from the best qualities, and used for fronts of buildings of a superior class.

Paviors—Excellent building bricks, sound, hard, well-shaped, and a good color.

Pickings—Good bricks, but soft and inferior to paviors.

Rough Paviors—Roughest sortings from the paviors.

Washed Stocks—Bricks in common use for ordinary brickwork, the commonest description of malms.

SECOND QUALITY—COMMON.

Grey Stocks—Good bricks, but of irregular color, and not suited for face work.

Rough Stocks—Irregular as regards shape and color, but hard and sound; not suited for good work.

Gizzlies—Tender, only fit for inside work.

COMMON QUALITY—INFERIOR.

Place Bricks—Only fit for common purposes, and not for permanent erections.

Shuffs—Unsound and *shuffy*, full of shakes.

Burrs or Clinkers—Used for artificial rockwork, cascades, et cetera.

Bats—Refuse.

Bricks are often adapted in shape to the purposes for which they are intended, either wedge-shaped for arches, round for chimnies, or rectangles of different forms. Sometimes they are constructed as *hollow* bricks, a form which, without impairing their strength, considerably diminishes their weight and cost in transport or carriage. A peculiar kind of brick is made at Berlin from the infusorial clay on the banks of the Spree, a cubic foot of which, weighing in the crude state sixty-one pounds, is reduced by drying and firing to twenty-five pounds seven ounces. Bricks composed of this earth weigh only one-fourth that of ordinary bricks of the same size. Bricks of this material, and containing ten per cent. of clay, were used for building the Museum in Berlin. Infusorial earth forms an admirable cement for clay in place of sand.

FIRE-CLAY goods are employed either for smelting,

as *crucibles*, or as *fire-bricks*, for lining furnaces, et cetera; their fire-proof qualities depending upon the amount of heat to which they are intended to be exposed, as a brick that would withstand the temperature of a limekiln may fuse in the heat of a porcelain furnace, and even those that withstand the highest temperature attained in manufactures will be fused, and frequently volatilized before the oxyhydrogen blowpipe, or between the poles of a powerful galvanic battery. As the success of smelting, and other operations in which high temperatures are required, depends so much on the material employed in the construction of the furnaces, and other apparatus, a general inquiry into this subject becomes necessary.

The fusibility of a substance is not solely influenced by the elements which enter into its composition, but also by the manner in which these elements are arranged and combined together. The chief constituent of clay—alumina—is a base which, in combination with silica, forms one of the most refractory substances, and this property is possessed by the clays in proportion as they are unmixed with other bases, as alkalies, oxide of iron, lime, and magnesia, in the order here given. In the purer clays, which for all ordinary purposes may be considered fire-proof, the refractory quality is augmented in proportion to the quantity of silica they contain.

In procuring fire-proof material, it is always desirable to obtain a chemical analysis; for, although this cannot supersede an actual trial, it is of the greatest service in guiding to the selection of the materials required to be added, in order to produce in the material the required properties. Such additions are generally necessary, as fire-clay must not only be infusible at the temperature to which it is exposed, but likewise free from liability to crack or fly, properties most important in the construction of *crucibles*. The chief cause of cracking is *contraction*, and this must be lessened by the addition of substances which do not themselves shrink, and at the same time do not impair the refractory nature of the clay. Pure sand, ground and free from lime and iron, and fire-clay previously burnt, are the substances most usually and appropriately employed. When fire-clay is brought into contact with substances exerting a chemical reaction upon it, and decomposing it by acting as a flux, it is much more difficult to obtain a ware capable of withstanding the combined action of heat and chemical affinity. An analysis of the most noted fire-clays employed in the construction of crucibles and fire-bricks is given in the annexed table:—

	Place of manufacture.	Silica.	Alumina.	Oxide of iron.	Magnesia.

Fire-clay wares require to be more strongly fired, in order to acquire an equal degree of solidity with those of ordinary clay—a circumstance partly occasioned by the large quantity of cement which enters into the composition of the mass. It is also of importance that the

wares acquire their maximum hardness and full amount of contraction before they are used. Crucibles do not always require firing, as is the case with the Passau crucibles, which are simply dried. Hessian crucibles, on the other hand, are burnt at about the same heat as

ordinary stoneware. The following table, according to BERTHIER, gives the elementary composition and rela-

tive proportions of the constituents in several kinds of smelting crucibles :—

Glass pots and retorts for the production of gas are, perhaps, the largest vessels at present constructed of fire-clay. The fire-clay retorts constructed by Messrs. JOSEPH COWEN and Company of Blaydon Burn, near Newcastle-on-Tyne, are sometimes as long as ten feet, with an internal width of three feet, and are constructed in one piece. In use they are found to be four times

as durable as iron. The material which furnishes these fire-proof wares consists of seven varieties of clay belonging to the coal formation, and which are found in the neighborhood of Newcastle-upon-Tyne. They occur below the coal, and are worked with them from the same pit. In color they are greyish-brown and full of vegetal remains. The analysis is as follows :—

	1.	2.	3.	4.	5.	6.	7.
Silica	51.10	47.55	48.55	51.11	71.28	83.29	69.25

Water and organic matter ..	10.47	12.01	10.67	12.29	6.94	3.64	7.50

By this it will be seen that the amount of silica in No. 2 is to the total amount of the bases as 100:85, while in No. 6, it is as 100:16. These clays are mixed together in certain proportions according to the purposes for which they are intended. The clay is not suspended in water, the coarser particles being ground into the mass, together with the addition of one-fourth part in weight of sawdust. The gas-retorts require to resist the sudden changes of temperature, which they undergo in the processes of firing and recharging, and average three inches in thickness to give them durability. These circumstances, combined with the Ω form of the retort, would inevitably cause them to crack, if the mass was not rendered excessively porous by the destruction of the sawdust in the firing. Powdered coke may be used for the same purpose, while the loss of gas from the porosity of the mass is prevented by the layer of carbon deposited on the interior surface during the operation. The retorts are either moulded and built up by hand with the plastic material, or formed by pressure in machines, somewhat similar to those described for pipe-making, but under pressure so enormous as sometimes to rend asunder iron cylinders between two and three inches thick. The drying and burning proceeds afterwards very slowly to avoid all chances of bursting of the retort when in use. The firing lasts fourteen days, and the retorts are of a pale-yellow color.

Newcastle-upon-Tyne also carries on an extensive trade in the manufacture of fire-bricks from the same clays above enumerated, and the preparation of which is as follows :—The clays, after exposure to the atmosphere for some time, are removed to the clay-mill, and ground up with fragments of the same clay previously burnt, from whence it is taken to the pug-mill for mastication before it is taken to the moulder. The bricks are then laid out to dry, and afterwards burnt in a kiln about fifteen feet long by fourteen feet broad, and ten feet high. Each kiln will burn

about fifteen thousand bricks at once. The operation of firing lasts five days. The bricks are placed on their edge lengthwise in the kiln. Stone-bricks of a very valuable kind, and used in the construction of the arches of reverberatory furnaces employed at Swansea in smelting copper-ores, are extensively manufactured at Neath in Glamorganshire. The materials of which the bricks are composed, are obtained from the neighborhood; they are subjected to a coarse crushing process under an edge-stone, and after mixing with a little water, are compressed into form by a machine, the coarseness of the mass rendering the moulding by hand impossible. This brick is fired in the ordinary way, but resists the action of intense heat better than the Stourbridge clay-brick. It expands more by heat, and does not contract to its original dimensions. The analysis of the three materials composing the mass is as follows :—

	From Penderyn.	From Dinns.	
Silica,	94.05	100	91.95
Alumina, with traces of } oxide of iron,	4.55	traces	8.05
Lime and magnesia,	—	traces	traces
	98.60	100	100.00

These bricks may therefore be called *siliceous* or *stone bricks*, and will no doubt prove admirably adapted for the construction of many kinds of chemical furnaces. A red fire-brick is likewise manufactured at Windsor, the analysis of the clay from which it is prepared being as follows :—

Silica,	84.65
Peroxide of iron,	4.25
Alumina,	8.85
Lime,	1.90
Magnesia,	35
	100.00

Or in mechanical mixture about seventy sand, and thirty parts clay.

QUININ.—*Quinia* or *quina*.—This important substance, which was discovered by PELLETIER in 1820, is found naturally in the bark of several species of *cinchona*, which inhabit the Eastern slopes of the Cordillera in Bolivia, Peru, and New Granada. Three principal species of bark occur in commerce—the yellow, true, or Calisaya bark, obtained from *cinchona cordifolia*; the red, yielded by *c. oblongifolia*; and the pale, from *c. condaminea*. It is found, also, though in smaller quantities, in a variety of barks, which are nearly all obtained from trees of the same family, the distinctive characteristics of which are but imperfectly known.

In the bark, quinin is associated with cinchonin, cinchonidin, cinchonidin, all possessing more or less basic attributes; kinic acid; cinchona red, which occurs in two forms, soluble and insoluble; a yellow and a green coloring matter; besides starch, gum, and lignin. The quinin exists partly as kinate, and partly in combination with cinchona red.

CONSTITUTION AND PROPERTIES.—Quinin is one of the more powerful organic alkalies. It generally appears, when pure, as an amorphous, resinous mass, of a dull white color. Its formula is— $C_{40}H_{24}N_2O_4 + 6\text{ aq.}$ It may also be obtained in six-sided prismatic crystals, which are a hydrate, containing six equivalents, or 10·5 per cent. of water, which are lost on fusion.

Quinin has an intensely bitter taste; it is inodorous, and fuses readily. It dissolves sparingly in boiling, and still more sparingly in cold water. It is easily soluble in ether and in alcohol, especially if hot, and is also soluble in the essential and fixed oils.

Ammonia decomposes the salts of quinin in the cold; but on the other hand, at the temperature of ebullition the ammoniacal salts are decomposed by this alkaloid. Tartaric, oxalic, and gallic acids, and the infusion of nut-galls, precipitate solutions of its salts. Quinin menstrua, if treated with chlorine gas, become yellow, rose-red, violet, and finally deposit a red resinous matter. A solution of the sulphate, saturated first with chlorine and then with ammonia, acquires a grass-green color, and deposits a green powder. With tincture of iodine, the solution yields a clear brown liquid, which on concentration deposits saffron-colored scales of a new compound. To detect small quantities of quinin, precipitate the suspected liquid with calcined magnesia, and evaporate to dryness; then extract with one part alcohol and two parts ether. Evaporate again to dryness, and extract with ether. Now prepare a test liquor, by saturating boiling water with ferridecyanide of potassium, to which, whilst hot, are added five volumes of the strongest chlorine water, and then ammonia, until the blackish-green liquid becomes very alkaline, when the sediment is filtered off. Now mix the fluid to be tested with excess of chlorine water, and drop in the test liquor. A blood-red color indicates the presence of quinin.

Or, put a minute particle into a watch-glass, drench it with five or six drops of pure sulphuric acid and an equal quantity of water, and add a fragment of bichromate of potassa. If quinin is present, the mixture will first assume a green shade resembling that of arseniate of copper, then a beautiful yellow green, and finally a

dark green. The sulphate, similarly treated, becomes first a nickel green, next a copper green, and finally a dirty-yellow. The above-mentioned reaction with chlorine and ammonia may also serve for the detection of quinin. Quinin combines with the acids, forming a series of well-defined and persistent salts, of which the sulphate is the most important.

SULPHATE OF QUININ, usually called the *disulphate*, $HO, C_{40}H_{24}N_2O_4, SO_3 + 7\text{ aq.}$, crystallizes in small silky tufts, or in fine acicular prisms; it has an exceedingly bitter taste, and when heated becomes phosphorescent. The dry salt is composed of one equivalent of quinin, one of sulphuric acid, and one of water. In the crystalline state it takes up, in addition, seven more equivalents, or 14·4 per cent. of water. It effloresces in dry hot air. It dissolves in thirty parts of water at 212° Fahr., but is very soluble in alcohol, especially with the aid of heat.

PREPARATION.—Quinin is generally prepared as sulphate.

The bark to be operated upon is in the first place submitted to a preliminary examination, in order to ascertain the amount of alkaloid which it contains. The safest method is to take about two pounds of bark, and to treat this by the common process for the preparation of sulphate of quinine.

GUILLERMOND proposes the following process for testing bark:—reduce the bark to powder, and treat this in a displacement apparatus with ten times its weight of alcohol of eighty per cent. Add to the alcoholic product thirty grammes of powdered quicklime for every two pounds and a quarter of bark, and agitate the mixture repeatedly. By this operation the liquor is almost completely decolorized. Filter off the sediment of lime, and add to the filtrate sulphuric acid, enough to produce the very faintest acid reaction. Distil off the bulk of the liquor, filter off the slight resinous precipitate, and concentrate the filtrate to crystallization. Others exhaust two ounces of the bark with eight ounces of water, and one scruple sulphuric acid. The mixture is kept for twenty hours at a temperature of 140°, and filtered. The digestion is twice repeated with similar quantities of acid and water. Mix and add ammonia as long as anything falls; filter, wash, dry, and weigh the precipitate. A prompt, though less accurate test, is the precipitation of a decoction of the bark by means of an infusion of nut-galls, the amount of alkaloid in the bark being estimated from the greater or less amount of the precipitate formed. The ordinary procedure for obtaining quinin is to exhaust the bark with dilute sulphuric acid, boil the extract with milk of lime, and extract the precipitate thus obtained with alcohol, from which, on concentration, the crude alkaloid separates in crystals. These are redissolved in dilute sulphuric acid, and purified by treatment with animal charcoal and recrystallization. A more perfect, though less rapid process, is as follows:—Pound the bark coarsely and let it steep in water, to which one-fifth of an ounce of hydrochloric acid has been added for every two pounds and a quarter of bark employed. Next morning boil the mixture for two hours, and strain. Submit the bark to a second and a third decoction in water containing

only half the above proportion of acid. Make, finally, a fourth decoction in pure water, and keep this for the first acid decoction of a fresh quantity of bark. The bark may now be thrown away. Mix the acid liquors, heat, and add carbonate of soda in slight excess, allowing the precipitate which forms to subside. Decant off the supernatant liquid, and test it by means of ammonia. Should this reagent produce a precipitate, the liquid must be precipitated once more with carbonate of soda. The whole precipitate is placed on a linen filter, and left to drain. It is next pressed and dried at a gentle heat. When perfectly dry it is reduced to powder, and treated from five to eight times with alcohol of eighty-six per cent., at the heat of the water-bath; squeeze the grounds each time, and filter the alcoholic liquors. The alcoholic fluid contains quinin and cinchonin, with coloring matters and some fatty substances. It is next very slightly acidulated with weak sulphuric acid, distilled, and the residue allowed to cool in the distillation apparatus.

A crystalline mass appears, which is drained on a linen cloth, to get rid of the black mother liquor. It is then washed with a little water. Make the crystalline mass, which is still highly colored, into a paste with warm water; mix with this animal charcoal in powder, and leave the paste till next morning. Mix the paste with a suitable quantity of water and boil, taking care to carry the concentration sufficiently far to obtain crystals upon cooling. For this purpose, it is preferable to divide the paste into several portions, and to treat them separately. Filter the liquid boiling. Upon cooling, the sulphate of quinin separates in perfectly white crystals. At the end of forty-eight hours let the mother liquor drain off, place the crystalline mass on some double folds of paper arranged on a hurdle, and carry them to the drying stove, taking care to keep the salt covered, since otherwise it would turn yellow. As soon as dry the salt must be removed from the stove, or it will effloresce and lose weight. The mother liquor which had deposited the white sulphate is next precipitated with ammonia, which throws down all the quinin and cinchonin still contained in it. Dissolve the precipitate with the aid of heat, in water acidulated with sulphuric acid, and add, towards the end of the operation, animal charcoal, and, if necessary, a little chalk to saturate the excess of acid. Seethe the liquid to a proper degree of concentration, and filter boiling. A fresh crop of white crystals will be deposited from the filtrate.

Treat the mother liquor of this second operation in the same way, and continue to proceed in this manner until the whole of the alkaloid is converted into crystallized sulphate. After the third precipitation it is sometimes advantageous to treat the precipitate with alcohol of sixty-four per cent., which dissolves the quinin alone, instead of dissolving it in water acidulated with weak sulphuric acid. A part of the alkaloid still remaining in the mother liquor is deposited spontaneously as sulphate, in course of time, and may be purified by the usual method. To extract the quinin still remaining in the mother liquor, the following process has been proposed by GUMOURT:—Add to the black mother liquor an equal weight of a solution of chloride

of sodium of 15° Beaumé. Boil for ten minutes, decant, and submit the brown deposit which has been formed twice more to the same operation. Pour the decanted liquors together, cool and filter, and precipitate the filtrate with ammonia. Redissolve the brown deposit which had separated from the saline liquid in the third operation in water, and add gradually, and in small portions at a time, ammoniated salt-water, taking care to stop short of complete saturation. Filter the liquid off the soft brown precipitate which forms, throw the latter away, and precipitate the filtrate with ammonia. Treat the several ammoniacal precipitates with alcohol. The solution, treated in the usual way, will now yield sulphate of quinin.

The quantities of sulphate of quinin furnished by the varieties of bark which occur in commerce are:—Two pounds eight ounces of yellow, or Calisaya bark, without rind, yield four hundred and ninety to five hundred and thirty grains sulphate of quinin. The same quantity, with the rind, yields three hundred and sixty grains. Two pounds eight ounces of the red bark, *c. oblongifolia*, will yield two hundred and forty-eight grains sulphate of quinin, besides about half that quantity of sulphate of cinchonin. Two pounds eight ounces of pale bark should yield one hundred and eighty grains sulphate of quinin, and one hundred and twenty-four grains of sulphate of cinchonin.

The following process, which has been patented by Mr. HERRING, yields a product not indeed perfectly free from color, but nowise inferior in its medical properties, and at least twenty per cent. cheaper than the common sulphate of quinin. Hence it is designated by the inventor *hospital sulphate*:—

First Operation, without Alcohol.—The powdered bark is boiled in a solution of caustic soda, pressed, returned to the boiling tub, agitated with cold water, again pressed, and if much color passes from the second washing the bark is returned to the tub, washed again with cold water and pressed once more. The treatment of the liquors obtained by the soda boilings and washings is described under the second operation. The decolored bark is now boiled with dilute sulphuric acid, kept in constant agitation by proper machinery, and this first boiling is run into the evaporating pan, a large water bath kept by steam pipes at a temperature of 120°, and agitated by the paddle wheels. The bark is again boiled with sulphuric acid and water as above, and the liquid run into the evaporating pan. The third, fourth, and fifth boilings are not evaporated, but reserved to extract the next portion of decolored bark that is brought forward. When the liquor from the first two boilings is sufficiently concentrated, it is allowed to cool, and filtered. Thus the flocculent coloring matter is separated, and the acid solution is now fit for precipitation. The filtered cold solution is treated by caustic soda, and the precipitated quinin is drained, washed, and pressed. It is now treated with dilute sulphuric acid, and crystallized into a very thick paste. When cold these crystals are pressed, washed, and again pressed. This removes the coloring matter and the chief part of the sulphate of cinchonin. The pressed cakes of sulphate are finally dissolved in a large quantity of water and recrystallized. The crystals

thus obtained from the hospital sulphate of quinin. The liquid which drains away from the second crystallization removes the small quantity of cinchonin which may not have been got rid of by the first crystallization. If the sulphate is required perfectly white it is redissolved, treated with *pure* animal charcoal, and again crystallized.

The patentee believes that in the ordinary method of making sulphate of quinin *impure* animal charcoal is absolutely necessary, though there is of course the risk of contaminating the product with the salts of charcoal.

Second Operation, with Alcohol.—The blood-red soda-boilings of the bark mentioned in the first operation are treated with hydrochloric acid, in order to retain in solution the alkaloids which have been extracted by the alkaline boilings. The ordinary view that quinin is insoluble in alkalies is pronounced erroneous by the patentee, who states, that in acting upon large quantities of bark the amount retained in solution is very considerable. The caustic alkalies exert less solvent power than the carbonates, and caustic soda least of all. After the red alkaline liquor has been acidulated with hydrochloric acid, it is concentrated and precipitated with lime. The precipitate, a mixture of quinin and lime, is washed, dried, and powdered, and finally extracted with hot alcohol. On distilling off the alcohol, the crude alkaloids are left behind. These are then treated with dilute sulphuric acid, exactly as in the former process, a larger quantity of water being required for removing the coloring matter and the sulphate of cinchonin. After two more crystallizations the sulphate is obtained perfectly pure.

The first operation yields from eighty to ninety per cent., and the second from ten to twenty per cent. of the required product.

USES.—Quinin is now very extensively employed in medicine as a tonic and febrifuge. For these purposes it is used in combination with sulphuric, citric, or valeric acid. The double citrate of iron and quinin is likewise very often prescribed.

ADULTERATIONS.—The consumption of this important remedy having greatly increased, whilst the superior varieties of cinchona bark are becoming yearly more scarce and costly, it is naturally subject to a great variety of adulterations. Amongst these may be enumerated chalk, sulphate of baryta, gypsum, boracic acid, gums, sugar, sugar of milk, starch, stearin, margarin, salicin, and phloridzin. Besides these intentional impurities, cinchonin and quinidin may be present if the preparation has not been conducted with due care. Phosphate of lime is also occasionally found, derived from the animal charcoal used in decoloring the alkaloid.

Mineral impurities may be detected by incinerating a portion of the sample in a platinum capsule. Pure quinin leaves no residue. Or a portion of the suspected quinin may be treated with alcohol at a gentle heat. Quinin dissolves, whilst any mineral matter which may be present, as well as gum, starch, stearin, will remain untouched. If a portion is burned upon platinum foil, sugar and margaric acid may be detected by their peculiar smoke and smell.

Sugar may likewise be detected by dissolving a known weight of the sample in water, and adding baryta, which precipitates both the quinin and sulphuric acid, if present. Any excess of baryta is now removed by a current of carbonic acid gas, and the liquid filtered and concentrated, when sugar, if present, is at once known by its taste. Gums and sugars may also be detected as follows:—Dissolve a weighed amount of the sample in water, and add a solution of pure carbonate of potassa, which precipitates both quinin and cinchonin. The precipitate may be filtered off, carefully dried, and weighed. Sugar and gum remain in solution. The liquid is now evaporated to dryness at a gentle heat, and the residue treated with weak spirit of wine, which dissolves the sugar, leaving gum intact. Filter off the clear liquid, and dissolve any residue in hot water. The aqueous solution is then tested with the sesquisulphate of iron, which precipitates gum as a yellowish jelly. If the sample is boiled in water, and the solution allowed to cool, starch may be detected by adding an aqueous solution of iodine, when the well-known blue or black tinge will appear. Starch, gum, and sugar may also be recognized on placing a little of the suspected sample in a porcelain capsule, and moistening with concentrated sulphuric acid. Quinin is merely dissolved, whilst starch, gum, and sugar are blackened. Ammoniacal salts are detected by titrating a portion of the sample with liquor potassæ, when an ammoniacal odor is evolved. If phloridzin is present, the sample turns a greenish-yellow in contact with sulphuric acid, and is discolored by the vapor of ammonia. If salicin be present to the extent of ten per cent. and upwards, the sample will turn a deep blood-red on the addition of concentrated sulphuric acid. In smaller proportions it may be detected by dissolving the sample in about six times its weight of concentrated oil of vitriol, and then adding twice the amount of water, when the salicin is precipitated, and may be filtered off and tested with sulphuric acid. If cinchonin be present the sample is dissolved, mixed with ammonia in excess, and well shaken up with ether. Quinin is dissolved, whilst cinchonin remains untouched, and may be separated by filtration.

The ordinary organic impurities may be detected by the following simple experiment:—A very small quantity is heated upon platinum foil, or in its absence, upon a silver spoon to fusion. Free quinin has then the appearance of oil of sweet almond; the pure sulphate a pale ruby red, the citrate a pale lemon or a deep yellow, if excess of acid be present. The valerianate remains unchanged in color. If adulterated, the residue will have neither polish nor transparency, and will be black and porous. The detection of the remaining cinchona alkaloids, if present in the salts of quinin, is more difficult. When submitted to optical tests, quinin and cinchonidin, according to BOIRCHARDAT and PASTEUR, are powerfully lævogyrate; quinidin and cinchonin pre-eminently dextrogyrate; and quinicin and cinchonin slightly dextrogyrate, upon plane-polarized light.

The ordinary tests for quinin, as mentioned above, distinguish between that alkaloid and quinidin on the one hand, and cinchonin, cinchonidin, and cinchonin on the other.

Oxalate of ammonia, when added to a solution of these alkaloids gives, after some hours, a crystalline precipitate of oxalate of quinin—if the liquid contain not less than one part of alkaloid in eight hundred of water—and a white precipitate in strong solutions of cinchonin. It does not precipitate cinchonidin or quinidin.

If hydriodic acid or iodide of potassium be added to neutral solutions, the following distinctions appear on crystallization:—The hydriodate of quinin appears as lemon-yellow prisms; the corresponding salt of cinchonidin in long thick colorless prisms; the hydriodate of quinidin in short hemihedral prisms; and that of cinchonidin in silky colorless prismatic needles.

RESINS.—*Resines*, French; *Harze*, German.—These are proximate principles found in most vegetals, and in almost every part of them; in some of them the quantity is very insignificant, whilst in others the resin is found in such abundance, as to render its extraction for industrial or medicinal purposes a profitable business, and it is to the latter class that the following particulars and descriptions apply. They are obtained chiefly in two ways; either by spontaneous exudation from the plants, or by extraction by heat and solvents. In the first case the discharge of the resin takes place, in the liquid state, from accidental punctures in the bark of the tree or shrub containing it, and also from artificial incisions penetrating the bark nearly to the hard wood. The substance which issues from these apertures is not a pure resin, but a mixture of it with volatile oil and other matters. In summer or the warm season the exudation flows freely, and the volatile oil being partly driven off spontaneously and partly resinified, the residue acquires considerable hardness. Should any of the volatile body remain, however, it is driven off on boiling the crude matter in water, and thus the resin is obtained free from all volatile oils.

When the coldness of the season prevents the flowing of the resinous body, the method adopted for its extraction is somewhat as follows:—The ligneous matter impregnated with the resin is reduced by rasping or grinding as fine as possible, and the powder boiled with strong alcohol. Many other matters besides the resin are thus extracted, and, on adding water to the spiritous extract, partly precipitate with it. By a fractional distillation of the menstruum most of the alcohol is recovered; and during the ebullition the finely-divided particles of resin collect and agglomerate in the aqueous fluid.

Resins possess the following general properties:—They are soluble in alcohol, insoluble in water, and melt by the application of heat, but do not volatilize without partial decomposition. They have rarely a crystalline structure, but, like gums, they seldom affect any particular form. They are almost all translucent, not often colorless, but generally brown, occasionally red or green. Any remarkable taste or smell which they sometimes possess, may be ascribed to foreign matter, commonly an essential oil. Their specific gravity varies from 0.92 to 1.2 Their consistence is also very variable. The greater part are hard, with a vitreous fracture, and so brittle as to be readily pulverized in the cold. Some of them are soft, a circum-

stance probably dependent upon the presence of a heterogeneous substance. The hard resins do not conduct electricity, and they become negatively electrical by friction. When heated they melt more or less easily into a thick viscid liquid, and concentrate, on cooling, into a smooth shining mass, of a vitreous fracture, which occasionally flies off into pieces like Prince Rupert's Drops; especially after being quickly cooled, and scratched with a sharp point. They take fire by contact with an ignited body, and burn with a bright flame and the diffusion of much fuliginous smoke. When distilled by themselves in close vessels, they afford carbonic acid and carbides of hydrogen, empyreumatic oil of a less disagreeable smell than that emitted by other such oils, a little acidulous water, and a very scanty shining charcoal.

The solution of resins in either hot or cold alcohol reddens tincture of litmus, but not sirup of violet; it is decomposed by water, and a milkiness ensues, out of which the particles of the resin gradually agglomerate. In this state it contains water, so as to be soft and easily kneaded between the fingers; but it becomes hard and brittle again when freed by fusion from the water. The resins dissolve in ether and the volatile oils, and, with the aid of heat, combine with the unctuous oils. They may be united by fusion with sulphur, and with a little phosphorus. Chlorine bleaches several colored resins if they be diffused in a milky state through water. The sulphide of carbon dissolves them. Concentrated mineral acids decompose resins under the influence of heat, the agents being likewise reduced. Strong sulphuric acid dissolves them in the cold; but on the addition of water, they again separate without decomposition. When heat is applied the sulphuric acid is broken up into sulphurous acid; at the same time carbonic acid results from the resin, and a carbonaceous residue with the artificial tannin of HATCHELL remains. Nitric acid aided by heat effects several transformations in resin, according to its state of concentration and the period during which its action is continued. Some resins yield, to this treatment, oxalic acid, and invariably artificial tannin may be obtained.

Most of them dissolve in solutions of the fixed alkalies, whether hot or cold, as also in ammonia, and form definite salts—resinates—some of which are quite neutral. These resinates are soluble in water, and form a considerable portion of the cheaper kinds of soap, being themselves possessed of detergent qualities. Resinates of the alkaline earths, and of the heavy metallic oxides, may be prepared from those of the alkalies by double decomposition; but they are insoluble, and generally strong acids liberate the resin from them unchanged.

Every resin is a natural mixture of several others, which sometimes admit of easy separation by different solvents, such as alcohol, ether, essential oils, alkaline solutions, *et cetera*. For instance, when certain acid resins are dissolved in alcohol, and an alcoholic solution of acetate of copper is added, it happens sometimes that only a part of the resin is precipitated. The deposit, which can be readily separated from the liquid, is found occasionally to be but partially dissolved by

other menstrua, and consequently admits of being separated into several definite substances. Again, many resins on being treated with a solution of potassa, soda, or ammonia, do not entirely dissolve; and inferring from this that the undissolved portion has not the same properties as that dissolved, the conclusion follows that two or more distinct principles were contained in it. The soft resins, which retain a certain portion of volatile oil, constitute what are called balsams, a full description of which will be found in Vol. I., page 224, *et sequitur*.

According to DUMAS the resins may be arranged in five classes, namely:—

1. Those which yield a volatile oil on being distilled with water, and leave an acid resin, or rather several resins possessed of acid properties, in the retort. To this class belong the several turpentine resins, balsam of copaiba, *et cetera*.

2. Those which yield a volatile oil when distilled with water and one or more acid resins, as in the foregoing; but in addition, a neutral one, generally capable of being crystallized. Animi, elemi, and caranna resins, mastic, vegetal, or palm wax, and several others, are of this order.

3. Resins which do not furnish a volatile oil on being distilled with water. Such are copal, amber, lac, betulin, and the like.

4. Resinous matters containing substances soluble in water of the nature of gum. Many of the members of this group have been already described as gum-resins, under GUMS, to which the reader is referred.

5. Balsams or compounds which contain, besides a volatile oil and an acid resin, cinnamic or benzoic acids, or some substances capable of producing them. It will be unnecessary to follow the description of the subjects coming under this class here, as they have been already described at some length.—See BALSAMS.

The Editor will now glance cursorily at each variety of resin in its alphabetical order, space not permitting of more.

AMBER.—*Succin*, French; *Bernstein*, German; *Succinum*, *Electrum*, Latin.—This interesting substance is frequently included among minerals, with which, however, it can no more be classed than the resin copal found in the sands of Africa. It is a substance of vegetal origin, resembling copal and other resins in appearance, and in some of its physical and chemical properties, and, like them, is employed for varnishes. The variation of its properties from those of ordinary resins is not, perhaps, greater than is to be found among the different members of the class, and may be in part attributed to a slight and gradual alteration effected during the time of its exposure to the various natural agents. From some of its chemical and physical properties and its occurrence in or near coal or lignite, it is usually supposed to be a resin derived from trees of the same geological age with the upper, secondary, or tertiary strata; but from the formation of succinic acid from fat, as well as from amber, one might suppose it to have been a species of wax, or to have a fatty nature. Its balsamic or resinous origin is more probable than the latter view. According to the traditions of the ancient Celtic nations, amber signifies tears shed by

APOLLO on leaving heaven for the famed Hyperborean island—Erin—and the account is thus happily recorded by BRYANT:—

The Celtic sages a tradition held,
That every drop of amber was a tear
Shed by APOLLO when he flew from heaven;
For sorely did he weep, and, sorrowing, passed
Through many a doleful region, till he reached
The sacred Hyperboreans.

Amber is most abundantly found on the Prussian coast of the Baltic, Courland, Livonia, Pomerania, and in Denmark, where it is often washed up on the shore by the waves, after the autumnal storms; or it is dragged up by a net, or obtained by mining. In the latter case a stratum of sand, then of loam, are pierced, neither containing amber; but below the latter occurs a bed of lignite, in and near which it is obtained. From the cones found near it, one may attribute the amber to the balsam of certain extinct species of coniferæ, which has hardened by the loss of its volatile oil. It frequently contains insects of various genera and species; among them several genera of spiders, no species of which is now in existence. Some genera of these insects are still found in South America and New Holland, but the species are extinct; and but a single living insect found in America has been observed in amber, namely—*lepisma saccharinum*. It is sometimes, but rarely, found on the Scandinavian coast; other localities are Hasen Island, Greenland, near London in sand, and Paris in clay, in Italy, on the Sicilian coast, in Spain, Siberia, China, and the United States, where it occurs in the red clay formation subjacent to the green sand, and sometimes in the green sand itself.

Thus it occurs frequently associated with lignite on Martha's Vineyard; from Amboy to below Camden, New Jersey; in the clays and sands of the deep cut on the Delaware and Chesapeake Canal, and in the green sand in Delaware; further at Cape Table, Maryland. It is said that Prussia draws an annual revenue of seventeen thousand rixdollars from this substance.

It is found of variable sizes; a specimen in the royal collection at Berlin weighs eighteen pounds. It is sometimes colorless, though usually some shade of yellow, light and brownish yellow, reddish-orange, brownish-black; it is transparent, translucent, opaque, sometimes milk-white and opaque, different hues and degrees of transparency occurring in the same piece; it has a resinous lustre, is rather brittle, has a conchoidal fracture, and a soft-feeling shining surface; it receives a good polish, and hence is carved into ornaments.

Specific gravity 1.065–1.075. By friction on woollen cloth it becomes strongly negatively electric.

Heated in the air it fuses at about 549°, evolving an agreeable aromatic odor, and burns with a clear flame. By fusion it is decomposed and its properties altered, giving off volatile matter and leaving a clear brownish translucent resin, which is almost insoluble in alcohol, partially soluble in ether, and most perfectly in fixed and volatile oils, with a brownish-yellow color. Slowly heated in linseed oil to boiling, it is soft and flexible, without fusing or decomposing, and, unless cooled slowly in the oil, is as brittle as glass; opaque spots are thus often rendered translucent.

Amber is wholly insoluble in water; absolute alcohol and ether become yellow in contact with it; when used on the substance powdered they extract succinic acid and resin.

It is soluble, with a brown color, in strong sulphuric acid from which water precipitates the greater part of a yellow color, which retains a little of the acid; by boiling with the same acid tannin and charcoal are produced. Nitric acid changes it to a yellow resin, which gradually dissolves in the acid. Finely powdered, and boiled with solution of caustic or carbonated alkali, much succinic acid is removed; and pure water extracts a resinote of the alkali from the residue, leaving amber bitumen.

By destructive distillation in a closed vessel an acid liquor containing acetic and succinic acids passes over; some crystals of succinic acid are then deposited in the neck of the retort, after which an empyreumatic oil is disengaged, at first thin and yellowish, but subsequently brown and thick; finally, a light-yellow wax-like sublimate appears in the neck of the retort, to which BERZELIUS has given the title of *crystallized pyrétine*, and GMELIN amber-camphor. The proximate constituents of amber are a volatile oil, succinic acid, two resins soluble in alcohol and ether, and a bituminous insoluble substance which constitutes the chief bulk of it; its ultimate analysis showed it to consist of carbon, hydrogen, and oxygen in the following proportions:—

	Centesimally.	
	Drassier.	Uro.
Carbon,	80.59	70.68
Hydrogen,	7.31	11.62
Oxygen,	6.73	7.77
Ash,	3.27	9.93
Loss,	2.10	
	100.00	100.00

USES.—Fine amber is used for making trinkets and ornamental objects; but its estimation is much greater in this respect in Oriental nations than with Europeans. The portion designed for ornamental work is split on a leaden plate on a lathe, and then smoothened to a shape on a Swedish whetstone; it is then polished with chalk and water or vegetal oil, and finished by rubbing with flannel. In these processes the amber is apt to become highly electrical and very hot, so much so as to produce nervous tremors in the wrists and arms of the workmen from the electricity. The artists guard against these effects, however, by working the pieces in rotation, so that the heat may not increase to an injurious degree, and the amber remains only feebly excited. The coarser kinds of amber are employed in chemical and pharmaceutical operations, and also for the manufacture of varnishes.

ANIME.—A resin not unlike copal, and of which there are two varieties, the American and the Oriental. The American anime is said to flow from incisions in the *hymenaea courbaril*, a tree growing in Brazil, Virginia, and the West Indies. The purer resin occurs in pale yellow pieces, with a vitreous fracture and dusty surface; softens in the mouth, tastes like mastic, and has an agreeable odor, especially when heated; specific gravity 1.03; combustible, and gives a lively flame. Warm oil of olives or lavender dissolves it;

it is wholly soluble in boiling alcohol, the solution reddening litmus, although the acid is scarcely extracted by water. Cold alcohol separates it into two resins; the soluble—54.3 per cent.—resembles the resin itself; the difficultly soluble resin—42.8 per cent.—precipitates from a boiling alcoholic solution, drying to a tasteless mass, slightly odorous and lighter than water. It also contains about 2.4 per cent. of a volatile oil, which passes off by heating *per se*, or with water. A brown variety does not soften in the mouth.

The Oriental anime, which has a specific gravity of 1.0272, appears to be a mixture of two resins, one pale-yellow, brittle, not softening in the mouth; the other reddish-yellow, softer; it does not contain the difficult soluble resin, and its alcoholic solution has a less acid reaction. It is not decomposed by nitric acid, even at the heat of fusion.

Anime was formerly employed in pharmacy, but is now chiefly used for scenting pastilles, and for varnishes; but it is rather a bad material for the latter, as it is dried with difficulty, and leaves the coating soft and pasty. For these reasons it is never used *per se*, but in admixture with other more suitable resins.

Botany Bay Resin, said to be the produce of *acarois resinifera*, is of a yellow hue, brittle, and of a slightly astringent taste. It exhales a fragrant odor when heated, and dissolves in alcohol and ether. It resembles tolu balsam in containing cinnamic, and a small quantity of benzoic acid.

COLOPHONY.—*Common Rosin*.—This is the residue remaining on the distillation of common turpentine; it retains more or less water, and is known as white and yellow resin, being in this state translucent, and often slightly viscid. When deprived of water by fusion, it is termed brown or black resin, colophony, rosin, or fiddler's rosin.

Rosin is a brittle, tasteless, and almost inodorous substance, of a smooth shining fracture; its specific gravity is 1.080. It softens at 160°, but does not enter into fusion under 275°. According to the analysis of BLANCHET and SELL, this substance, in its pure state, may be represented as composed of $C_{40}H_{30}O_4$; but UNVERDORFEN has shown that colophony includes two distinct acid resins, together with a minute portion of an indifferent one. These acid resins he designates pinic acid, and silvic acid, the former greatly preponderating. As respects the composition of these acids, it appears that they are isomeric, and therefore have the same formula as that above ascribed to pure colophony, a conclusion sanctioned by ROSÉ and TROMMSDORFF, but not by LÖWIG.

Rosin forms an important ingredient in the composition of yellow soap, and is a partial substitute for fixed oil or fat; it is not analogous to the latter in chemical constitution, nor can it, like those bodies, form with an alkali a proper soap by itself. Colophony contains no glycerin, nor any equivalent for that substance.

The formation of yellow soap from rosin depends on the direct combination of the resin acids with soda. No glycerin is eliminated, there being no proper saponification. The compounds formed, however, by the union of soda with rosin are not separable from their

aqueous solutions by chloride of sodium, like true soda soaps, nor do their concentrated solutions become mucilaginous or gelatinous on cooling; nevertheless they produce a lather, and, when added to soap in limited proportion, increase its detergency. Rosin is also used to some extent in perfumery.

This resin is largely employed in manufacturing industry for the purpose of extracting the various oily bodies it produces by destructive distillation, and which oils are largely consumed in the arts, as well alone as for adulterating dearer kinds. The bleaching of common colophony has long engaged attention, but success did not attend the various efforts. Latterly, however, Messrs. HUNT and POCHIN's patent seems to have accomplished the task of converting the common black resin, worth four to five shillings per hundredweight, into a white almost transparent compact article, which is said to be highly beneficial to soap and varnish makers, and worth as much as fifteen shillings per hundredweight.

Their process may be here advantageously although cursorily described. It consists in distilling resins and resinous substances without decomposition, or only partially so, by which they are freed from various mechanical impurities, and at the same time almost deprived of their color. The ordinary rosin of commerce, *et cetera*, are taken and introduced into an iron or other suitable vessel; they are then melted, and steam is passed, during the entire period of the operation, through the fluid mass, until the whole, or nearly the whole, has been distilled. The rosin is condensed in a suitable receiver, kept as cold as it can be by the application of water, and exsiccated; it is then adapted for the purposes for which it is required. During the distillation the temperature rises from about 390° to 600°, at which it is maintained until all such portions of the contents of the still as are capable of being volatilized have passed into the receiver. Instead of steam, carbonic acid, or a mixture of carbonic acid and nitrogen, or hydrogen gas or carbides of hydrogen, are introduced to decolor the resin.

COPAL, said formerly to have been derived from *rhus copallinum* and the *eleocarpus copalifer*, seems by late accounts to be obtained from various species of *hymenæa trachylobium* and *vonapa*. Several varieties of this resin are known in commerce, which are apparently the product of different trees, natives of Africa, America, the East Indies, and New Zealand. Levant copal is considered the best, and is met with in moderate-sized round masses, hard, transparent, colorless, or but slightly lemon yellow. *It is, of all resins, that which makes the finest varnishes.* Two kinds of copal resin are known; one hard or true, and the other tender or fictitious copal. The true variety, as above stated, is met with in large pieces, colorless, or of a slight yellow shade, exteriorly opaque, but limpid in the interior. In some cases its tint approaches to a brown. Insects are occasionally found inclosed in it, but more rarely the debris of plants.

It has so much resemblance to amber that it might be supposed to have a fossil origin; at all events it has probably been long exposed to the action of the air before being collected. It is very hard, and breaks

with a conchoidal fracture. Exposed to heat it softens, but does not permit its being drawn into threads; when the temperature is more elevated it melts, and at the same time undergoes decomposition, and distributes on boiling a vapor having the peculiar odor of the wood of the aloe tree. Its specific gravity varies from 1.045 to 1.139. In the natural state copal is only slightly soluble in absolute alcohol; on boiling it, however, it tumefies, and forms a viscous elastic mass; with ether it acts in a similar way, but ultimately dissolves. When it is desired to dissolve it in alcohol *per se*, the best method is to suspend it in the vapor of the boiling liquid, and it gradually falls drop by drop and is perfectly dissolved; with oil of turpentine, under similar treatment, the result is the same. To avoid the loss of spirit and other inconveniences which attend this process, many trials have been made. One of these, though singular, is said to be effective; it is to grind the resin and expose it to the air for a period of ten or twelve months, after which it is readily taken up by spirit of wine. It may be dissolved in absolute alcohol by first acting on it with ammonia, which softens it into a gelatinous mass, and then adding the spirit in small portions, with the aid of heat. It may likewise be dissolved in alcohol after being softened with ether.

The ordinary practice is, however, to take advantage of the property which certain essential oils have of softening the resin, and thereby rendering it more readily soluble. A quantity of the copal is taken and moistened with oil of rosemary or of lavender; after standing for a time some pieces begin to soften, while others are unaffected; the former are selected for spirit varnish, and the latter are put by for varnish to be made with fixed oils. The first portion is then ground, moistened a second time with either of the essential oils named, and after a short time it swells up to a pasty mass, which on addition of the necessary quantity of spirit of wine dissolves. Spirit of turpentine behaves in like manner. The same menstrua, provided a little camphor be first dissolved in them, readily take up the resin; but the varnish thus formed, as also that prepared by means of oil of rosemary, is soft and devoid of the durability which the real spirit varnishes made with the resin possess. But the common copal varnish is made by melting it cautiously, and adding oil of turpentine heated to a certain point.

According to UNVERDORPEN and FILHOL, who have more recently examined Indian copal, it contains no less than five definite compounds of a resinous nature, four of which possess acid and one neutral properties. Thus, in treating powdered copal with a spirit containing sixty-seven per cent. of alcohol, and adding to the extract thus obtained an alcoholic solution of acetate of copper, a precipitate of bluish flocculi appears, which on being dried and affused with cold ether takes up resin A; the alcoholic liquid retains resin B in solution. Further, on treating the residue with absolute alcohol, a third resin, C, is dissolved together with portions of the two preceding ones; and, finally, by treating what remains from the last menstruum with potassa, a fourth resin, D, separates, and a neutral substance, E, remains.

The analysis of copal, according to FILHOL, is as follows:—

	Bombay copal.	Madagascar copal.	Calcutta copal.
Carbon,.....	79.70	79.80	80.66
Hydrogen,..	9.90	10.78	10.57
Oxygen,....	10.40	9.42	8.77
	100.00	100.00	100.00

The composition of the resin alters, however, on being exposed to the air for some time in a finely-powdered state, or when reduced to an impalpable powder by abrasion under water, oxygen being absorbed, as the following analyses illustrate:—

	Copal exposed to the air in fine powder.	Copal reduced to an impalpable powder under water.
Carbon,.....	77.0	71.4
Hydrogen,.....	10.0	9.2
Oxygen,.....	13.0	19.4
	100.0	100.0

Tender or fictitious copal is found in commerce mixed sometimes with a little Indian copal, but it is brought from the Brazils without any admixture. That from India is vitreous, translucent, and nearly as transparent as glass, but age communicates to it a shade of yellow on the surface. Its ordinary form is in tears; it possesses a weak, agreeable odor, is very friable, and preserves this property even in the varnish made with it, on which account it is not so much esteemed. Heat renders it soft and elastic, so that it can be drawn out into threads as fine as silk. Alcohol partly dissolves it, the residue appearing like gluten. Ether takes up nearly the whole substance.

FILHOL has analyzed this resin and found it gave—

Carbon,.....	85.3
Hydrogen,.....	11.5
Oxygen,.....	3.2
	100.0

Dammara Resin is a white resin brought from the East Indies, and is said to be the produce of the *pinus dammara*; it contains a resin soluble, and one insoluble in alcohol.

Dragon's Blood, which is a deep-red resin imported from the East Indies, has been fully described, although erroneously, under BALSAMS, in vol. i., page 227.

ELEM.—It appears that the source from which this resin is obtained is very doubtful. It is generally described as constituting a member of the *Amyrideæ*, which is allied to the class to which the orange-tree belongs, owing to LINNÆUS confounding apparently two distinct plants under one name—the *amyris elemifera*—namely, the *icica icicariba* and the *amyris plumieri* of DE CANDOLLE; the former a Brazilian tree which yields, according to PISON, a resin similar to the so-called *gum-elemi*, and the latter a native of the Antilles, which likewise produces a resin. PEREIRA, in tracing the source and origin of this resin, found that it was imported entirely from Amsterdam and Hamburg, and concluded that it was the product of a Dutch settlement. He is inclined to believe that which formerly came from Ethiopia by way of the Levant was derived from the *canarium zephyrinum* or *canari*

barat of RUMPHIUS, who says that it yields a resin so like elemi that it might be taken for it. PEREIRA mentions three kinds of elemi—elemi in flag leaves, elemi in lumps, and Brazilian elemi. The first is imported into England from Holland in triangular masses of one to two pounds weight, enveloped in palm leaves. The elemi in lumps is a little paler in color than the Brazilian. MARTIUS states that the first variety is the product of the *amyris zeylanica*; though PEREIRA doubts the assertion, on the ground that if it were a product of Ceylon it would be imported direct hither, which is not the case. The only doubt which he seems to throw upon the Brazilian elemi being derived from the *icica icicariba*, which may be taken for the *amyris elemifera* of LINNÆUS, rests upon the certainty of its being a Brazilian product.

In extracting the Brazilian elemi, an incision is made into the stem of the tree, whence the juice exudes, and the resin is gathered in twenty-four hours afterwards. It is imported in cases containing two or three hundred pounds each. It is soft and unctuous, but becomes hard and brittle by cold and age. It is semitransparent, of a yellowish-white color, mixed with greenish points; its odor is strong, agreeable, analogous to that of fennel. This is owing to a volatile oil, which may be obtained from it by dry distillation.

The description most extensively dealt in, is that which is brought to this country from Singapore in a soft, strong-smelling mass, in cases of about two hundredweight. It is the produce of Manilla, and the Editor is credibly informed that it is not imported from any part West of Singapore. In addition to this, the Brazil sort is occasionally seen in the market.

The proximate principles of elemi are a transparent resin having acid properties, soluble in cold alcohol; a second resin taken up by boiling alcohol, but deposited from the solution on cooling in a crystalline state; a volatile colorless oil, which, according to DEVILLE, resembles much the essence of turpentine, and of citron in composition, as in its reactions; and a bitter extractive. The annexed per centages were found by BONASTRE:—

Volatile oil,.....	12.5
Resins soluble in both hot and cold alcohol,...	60.0
Resins soluble in hot, but not in cold alcohol	24.0
—elemi,.....	
Bitter extractive,.....	2.0
Impurities,.....	1.5
	100.0

The resin *a*, readily soluble in cold alcohol, consists, according to JOHNSTON, of $C_{40}H_{32}O_4$, while the resin *b*, sparingly soluble in cold alcohol, is composed of $C_{40}H_{32}O$. Specific gravity, 1.08 BONASTRE; SCHUBART gives it 1.055.

Elemi is occasionally used as a topical remedy in the form of an ointment, more particularly in ulcerous complaints of an old and indolent nature. It is extensively employed for varnishes.

GUAIACUM.—This substance, which is commonly, though very erroneously, denominated gum-guaiaicum, is the produce of the *guaiacum officinale*, a lofty tree, native of St. Domingo and Jamaica. It occurs in tears naturally exuding from the stem; and in lumps ob-

tained partly from incisions into the trunk of the tree, and partly by the action of heat upon billets of the wood. This resin is of a dark-green dingy color, transparent when in thin laminae, and of a brilliant resinous fracture. It has a slight balsamic odor. Its powder is at first pale grey, but gradually deepens, and becomes green by exposure: it acquires a beautiful but transient blue tint when moistened with spirit of nitrous ether. According to the Edinburgh Pharmacopœia, the characters of guaiacum resin are as follows:—Fresh fracture red, slowly passing to green; the tincture slowly strikes a lively blue color on the inner surface of the paring of a raw potato. The specific gravity of guaiacum varies between 1.20 and 1.23. It is soluble to the extent of about ninety per cent. in absolute alcohol. The insoluble portion, though sometimes described as resin, has more of the characters of altered extractive. When subjected to dry distillation, guaiacum fuses at about 570°, and an oily matter, together with water, passes over, which has been examined by SOBRERO, and by PELLETIER. When chewed, guaiacum softens under the teeth, but has scarcely any taste, though it leaves a burning sensation in the throat.

Physiological Effects.—Guaiacum resin is an acrid stimulant, formerly very much used in medicine, and even now to a great extent.

Under the use of small and repeated doses of guaiacum various constitutional diseases sometimes gradually subside, and a healthy condition of the system is brought about with no other sensible effect of the remedy than perhaps the production of some dyspeptic symptoms, and a slight tendency to increased secretion. One designates this inexplicable, though not less certain, influence over the system by the term *alterative*. When guaiacum is given in *moderately large doses*, or to plethoric, easily excited individuals, one observes the combined operation of an acrid and stimulant. In very large doses guaiacum causes heat and burning in the throat and stomach, vomiting, purging, pyrexia, and headache. In its operation on the system guaiacum is allied to the balsams.

JALAP.—The resinous portion of jalap is the most important. Jalap resin is obtained by mixing the alcoholic tincture of jalap, prepared by percolation or digestion with water. The precipitated resin is to be washed with warm water, and then dissolved in alcohol. By evaporation the tincture yields the resin. PLANCHÉ has proposed another process. By digestion with animal charcoal, the alcoholic solution of the resin is rendered nearly colorless, and by evaporation yields an almost colorless resin. Jalap resin is soluble in alcohol, but insoluble in water. Triturated with milk it does not form an emulsion, but its particles unite into a solid mass. By this it may be distinguished from scammony resin.

Physiological Effects.—Jalap resin is a local irritant. It acts as a powerful and drastic purgative. To scammony it is closely allied, not only by its effects, but also by botanical affinities and chemical properties. It is much less irritant to the intestinal mucous membrane than gamboge; and, therefore, is a much safer purgative.

Adulteration.—Commercial resin of jalap is rarely,

if ever, obtained in a state of purity. Guaiacum resin is the substance most frequently found mixed with it. Two methods have been pointed out for detecting this fraud—one by means of ether, the other by nitrous gas. Ether dissolves guaiacum very well, but does not dissolve resin of jalap. With nitrous gas the process consists in dissolving a small quantity of the suspected resin in spirit of wine, soaking a piece of white paper in this liquid, and exposing the paper to the action of nitrous gas. If the alcoholic solution of resin of jalap contain guaiacum, the paper should assume a blue tint; if no guaiacum be present, the color will remain unaltered.

MASTIC is the produce of the *pistacia lentiscus*, native in the South of Europe, the North of Africa, and the Levant, particularly the Island of Chios. It occurs in small spheroidal translucent tears, of a pale yellow hue, vitreous fracture, agreeable odor, and mild aromatic taste. When chewed, it becomes tough and somewhat viscid; it fuses at about 250°, and begins to be decomposed; it contains a very minute quantity of volatile oil. Mastic is a valuable ingredient in certain varnishes, and is frequently used for the purpose of stopping decayed teeth. It is not employed in medicine. Its produce is commonly known under the name of *pounce*.

SANDARACH, or Juniper resin, is the produce of *thuja articulata*, which grows in Barbary. It is imported from Magadore, and largely used as an ingredient in varnishes. It usually occurs in small yellow brittle drops, easily fusible, and soluble in alcohol.

SCAMMONY RESIN.—The substance known in pharmacy under the name of *scammony*, is an exudation from incision of the root of the *convolvulus scammonia*, and appears first as a milky juice, which afterwards dries. It is often very considerably adulterated. Several varieties of this drug come into the market, but the most select is imported from Smyrna, and occasionally from Trieste, under the name of *virgin* or *lachryma scammony*. It is of a dark-greenish grey color, moderately hard, and of a somewhat resinous fracture. It should not effervesce with hydrochloric acid, nor should its cold filtered decoction be blued by iodine. One hundred grains, when incinerated with nitrate of ammonia, should not yield more than about three grains of ashes: ether should abstract from it at least seventy-eight per cent. of resinous matter. The odor of scammony, especially when breathed upon or moistened, is peculiar; and when a little water is rubbed upon its surface it should easily lactify.

THE RESIN OF SCAMMONY, obtained by evaporating its ethereal solution, is transparent, and of a brown tint, but may be decolorized by animal charcoal. Its alcoholic solution is feebly acid, and water throws down from it the resin in the state of hydrate. According to JOHNSTON, it is remarkable as containing more oxygen than any other resin hitherto analyzed. It is a powerful cathartic.

LAC.—*Laque*, French; *Gummilack*, German.—This resin is produced by the female of a small insect—the *coccus lacca*, or *coccus ficus*—which feeds and fecundates upon the banyan or religious tree of the Hindoos, and several allied plants, such as the *ficus indicus*, *ficus*

religiosa, the *rhamnus jujuba*, the *croton lacciferum*, and the *butea frondosa*.

In November or December the young brood makes its escape from the eggs lying beneath the dead body of the mother; they crawl about a little way, and fasten themselves to the bark of the shrubs. About this period the branches swarm to such a degree with the vermin that they seem covered with a red dust, in which case they are apt to be dried up and exhausted of their juice. Many of them, however, adhering to the feet of birds, become their prey, and are carried off by them to other trees. They soon produce small nipple-like incrustations upon the twigs, their bodies being apparently glued by means of a transparent liquid, which goes on increasing to the end of March, so as to form a cellular texture. At this time the animal resembles a small oval bag, without life, of the size of the cochineal. At the commencement a beautiful red liquor only is perceived, afterwards eggs make their appearance. In October or November, when the red liquor becomes exhausted, twenty or thirty young ones bore a hole through the back of their mother and come forth. The empty cells remain upon the branches; they are composed of the milky juice of the plant which serves as nourishment to the insects, and which is afterwards transformed into the red tinctorial matter which is found mixed with the resin; but its quantity is greater in the body of the insect than in the eggs, and more particularly in the red liquor secreted for feeding the young. After the escape of the insect the cells contain much less coloring body, and, consequently, the collection of resin ought to take place before that time by breaking off the twigs and drying them in the sun. In the East Indies this operation is performed twice in the year—the first time in March, and the second in October.—*Ure*.

The dried branches and twigs are called *stick-lac*, which serves the double purpose of dyeing, varnish-making, and sealing wax.

There are several varieties of stick-lac. According to quality that of Siam is considered the best, the Assam stick-lac ranking next, and the third quality is produced in Bengal. The analyses of the stick, seed, and shell lac are here collated:—

Lac as brought to Europe is in various forms, such as grains, lumps, and thin scales; the former is called *seed-lac*, and is the residue after the resinous matter scraped off the stick-lac, ground and boiled in water to remove the greater part of the coloring matter, and dried in the sun; the second is called *lump-lac*, and is merely the former melted into lumps; and the third, which is named *shell-lac*, is of the same nature as the seed and lump-lac, only purer. It is usually prepared in India by heating the seed-lac in bags over a fire, and by squeezing and pressing, causing the liquefied resin to flow out and fall upon the smooth surface of the stems of the banyan-tree; the coatings thus formed on cooling harden and constitute shell-lac.

It will be seen from the preceding tables that the proportion of resin is much larger in shell-lac than in any of the other commercial forms of the resins. The better quality of the article is of a light-brown hue passing into orange, and sometimes to a deep ruby color, whence the names *orange* and *ruby* shell-lac; the inferior kinds are much less transparent, darker in color like glue, and in thicker plates.

By exposure in thin shreds to the sun's rays, or in a finely-divided state to chlorine water, or by reducing it to a fine powder, suspending in water and passing hydrochloric acid vapor into the menstruum, the dark-colored varieties are bleached. When this is done, however, the resin loses many of those qualities that so admirably recommend it for some kinds of varnishes, but it answers well for making sealing-wax.

Lac resin is very difficultly soluble in alcohol, though, like copal, it may be completely taken up by this solvent. Like most of the other resins, it has a strong affinity for bases, with which it forms definite compounds. Dilute hydrochloric acid and acetic acid dissolve the resin freely, but not the strong sulphuric acid. Borax solutions with the aid of heat also take it up. The portion soluble in alcohol has a specific gravity of 1.139. UNVERDORPEN found it to be a compound of several resins, namely—

1. Resin soluble both in alcohol and ether. 2. Resin soluble in alcohol, insoluble in ether. 3. Resin but very slightly soluble in cold alcohol. 4. Crystallizable resin. 5. Resin soluble both in alcohol and ether, but not in petroleum uncrystallizable. Besides these, a saponifiable fat wax and coloring matter have been detected in shell-lac.

SILVER.—*Argent*, French; *Silber*, German; *Argentum*, Latin.—This is one of the precious metals, and is characterized by its perfectly pure white color. Its combining weight is 108; its symbol, Ag. Melted, its density is 10.47; hardened under the hammer, it becomes 10.54. Its specific heat is 0.057. In malleability it is only inferior to gold, and may be beaten into leaves of less than one-hundred-thousandth of an inch in thickness, and drawn into very fine wires. It has also considerable tenacity, a wire of one-hundredth of an inch in diameter supporting a weight of twenty-three pounds. It is harder than gold, but softer than copper, and when pure it is so soft as to be cut by a knife. The addition of a small quantity of copper increases its hardness.

Silver melts at a full red heat, corresponding to

1870°; but in consequence of its pure white color, and the high lustre which it is capable of receiving, its reflecting power for light and heat is greater than that of any other metal, and, therefore, when perfectly polished, it does not melt in the focus of a mirror capable of fusing platinum. For the same reasons, its radiating power is so low that a silver vessel retains the heat of a liquid contained in it longer than a vessel of any other metal.

HISTORICAL NOTICE.—The discovery of silver appears to have been coeval with that of gold, and dates back to the earliest times of human history. In the book of Genesis it is stated that ABRAHAM, who lived about two thousand years before the Christian era, was rich in cattle, and in silver, and in gold; and on the death of his wife he purchased a field for a burying-place, the payment for which was made with four hundred shekels of silver, which he delivered not in coin, but *by weight, according to the currency of the merchants*. JOSEPH, the great grandson of ABRAHAM, was sold by his brethren to a caravan of Arabian merchants for twenty pieces of silver; and when he was established in Egypt as minister of the king of that country, his brothers brought *silver in their sacks' mouth* to purchase corn during a season of scarcity. Afterwards, when making himself known to his family, JOSEPH presented to his younger brother, BENJAMIN, three hundred pieces of silver. The author of the book of Job, who is certainly a very ancient writer, not only speaks of *the dust of gold*, but says, *Surely there is a vein for the silver, and a place for the gold where they find it*; so that he seems to have been well acquainted with the fact that silver was found in veins, and gold commonly in small particles. The vast amount of the precious metals accumulated by DAVID and SOLOMON has been mentioned in the article on GOLD, and in the first book of Kings it is stated that all the vessels of the house of the forest of Lebanon were of pure gold; *none were of silver, for that metal was nothing accounted of in the days of SOLOMON*, and, in short, *the king made silver to be as stones in Jerusalem*.

The accounts given by the profane writers of antiquity are equally surprising, and some of them altogether incredible. In POLYBIUS, for example, is found a description of Ecbatana, at a period subsequent to the capture of that place by ALEXANDER, in which it is stated that the beams, the roofs, and the pillars which supported the porticos and peristyles of the palace, were all covered with plates, some of silver and some of gold. The tiles, likewise, were all of silver. Though the place had been three times plundered before ANTIOCHUS arrived, there were still remaining in the temple of Ena some pillars cased with gold, and a large quantity of silver tiles, laid together in a heap. CRÆSUS, king of Lydia, who lived about five hundred and forty years before Christ, and whose wealth has become proverbial, is stated by HERODOTUS and DIODORUS to have made presents to the temple of Delphi amounting to four thousand talents of silver and two hundred and seventy talents of gold, or near three millions in value of British money.

The principal sources from which the ancients obtained their gold have been mentioned in the article

on that metal, and probably much of their silver was obtained from the same localities. PLINY speaks of a people named the Dardaneans, who inhabited a country the richest of all India in gold mines, and the Selians, he says, have the most abundant mines of silver. The chief sources of the wealth of the ancient kings of Egypt were the mines of the neighboring countries of Nubia and Ethiopia, which produced not only copper in abundance, but also gold and silver, before iron was known in Africa. According to XENOPHON, the Athenians worked the silver mines of their own country—Attica—from an unknown age, as well as the gold mines in their foreign possessions in Thrace, and in the island of Thasus. Epirus also had silver mines, which continued to be worked in the time of STRABO; but it appears probable that, for a long time, the only ore that was used was that found near the surface. The Colophonians were the most celebrated among the Greeks for their skill in smelting gold, but none of them were equally expert in smelting silver; for, according to STRABO, their successors were enabled to separate the silver from the residual earths with a profit, although even the latter were much inferior in skill to modern metallurgists.

But the country most productive of the precious metals, and especially of silver, in very remote ages, was the Spanish peninsula, which many authorities assume to have been the Tarshish of the sacred writings, to which a commercial expedition was sent by SOLOMON. It is certain that Spain was visited and colonized by the Phœnicians at a very early period, and that continual intercourse was maintained between the colonists and the mother country, as well as with the future descendants of the same race, the sons of Tyre and Sidon, who founded Carthage. The story of the discovery of the mineral wealth of the country, as related by DIODORUS, resembles many of the fables which in ancient times were dignified with the name of history. He states that the Pyrenean mountains were covered with thick woods, which were set on fire either by the shepherds or by lightning, and continued burning so long that the heat melted the minerals, in consequence of which the silver, with which the soil abounded, ran down into the valleys like a stream of water! He adds, that as the inhabitants were unacquainted with its value, they readily exchanged it with some Phœnician traders, who accidentally visited their shores, for some trifling articles of ornament. The traders loaded their vessels with the precious metal till they could carry no more, and then cut their leaden anchors from the bows, and replaced them with others of silver. These statements are extravagant; but there is no doubt that in ancient times a vast amount of silver was successively extracted from Spain by the Phœnicians, the Carthaginians, and the Romans, and exported to all parts of the world in exchange for merchandise.

Gold, iron, and lead were procured in the South, and some tin in the North of Spain; but the gold was probably of small amount, and silver was the chief mineral wealth of the country. Of this mineral PLINY says it was found in all the Roman provinces, but the best in Spain, and that in a barren soil, even in the

mountains; and wherever one vein was discovered, another was found not far from it. He mentions, as a very singular fact, that the mines begun by HANNIBAL still existed in his time, and retained their original names. One, which was still called Bebulu, from the discoverer, had formerly supplied HANNIBAL with three hundred pounds weight of silver daily. This, he adds, was effected by means of passages under the mountain a mile and a half in length, in which the laborers, standing in water, worked night and day by lamp-light to draw off the water, which at length accumulated to such an extent as to form a large river. JACOB, in his *History of the Precious Metals*—an elaborate work, to which the Editor is chiefly indebted for the facts condensed into this historical notice—states that the situation of the mine mentioned by PLINY is at present well known to have been at Guadalcanal, in the modern province of Cordova, at the foot of the Sierra Morena; and, judging from what has been surveyed of it in more recent times, the water, which was imperfectly drained by the costly subterranean tunnel noticed by PLINY, has long since overflowed the whole interior of the mine; but whether it was exhausted of its treasure and abandoned on that account, or whether it was destroyed by the influx of the water, cannot now be ascertained. It is interesting to remark that HANNIBAL chiefly derived from the silver wealth of Spain the sinews of war, which enabled him to shake to its foundations the Roman empire; and, for many years, he greatly over-worked the mines of that country in his eagerness to accumulate and hoard immense treasures, with a view to the accomplishment of the one great object on which he had set his whole heart.

During several centuries of profound darkness which succeeded the overthrow of the Roman empire, mining operations appear to have been suspended throughout Europe, and the dates at which they were generally resumed are not precisely known. The chief sources of mineral wealth in the middle ages were the Austrian mines, or at least those which existed in countries that are now included within that empire; and, of these, it is considered probable that the mines of Chemnitz and Kremnitz in Hungary were those first worked. FERBER dates the opening of Chemnitz in 745, and that of Kremnitz in 770; but AGRICOLA, who states that they had previously been worked by the Romans, dates their reopening nearly a century earlier. The silver in these mines is chiefly found in lead, in a proportion varying from two to twenty ounces of silver in a hundred pounds of the baser metal. In Bohemia there are celebrated mines of silver at Joachimsthal, in the circle of Saatz, but at what period the workings in them commenced does not appear. In some of these mines the galleries have been carried to the extent of five thousand six hundred fathoms, and some of the shafts are three hundred and fifty fathoms in perpendicular depth. At Altenberg, also, the metals were found in beds of gneiss, in which were mingled felspar and granite; but the mines of Schellgadin are at present the most important. These were also originally worked by the Romans, and the earliest records of their resumption date back to 1378. In the

Tyrol, near Brixen, are silver mines, which, during the excitement in the sixteenth century occasioned by the discovery of the mineral treasures of America, obtained the name of El Dorado. In the year 1523 they produced three thousand eight hundred pounds of silver, but subsequently they decreased in value, and have long been discontinued.

The mines of Saxony, says JACOB, were first discovered in the tenth century, when the whole district in which they are situated was covered with wood, and without inhabitants. Some carriers from Halle, on their way to Bohemia, observing metallic substances in the tracks made by the wheels, took them up and sent them to Goslar to be examined, when they were found to consist of lead with a considerable quantity of silver. This led to the establishment of mining operations, which have continued from the year 1169 to the present day. For some years in the fourteenth century the mines of Schneeberg are said to have yielded so large a portion of silver, that the tithes on it amounted in thirty years to three hundred and twenty-four thousand quintals; but these latter mines have long been exhausted.

The mines in the Hartz forest in Germany, which, at the time of this discovery, formed a portion of Saxony, are now partly in the dominion of Hanover, and partly in that of Brunswick. There are various conflicting opinions respecting the discovery of the mineral wealth of the Hartz. The most probable accounts fix it in the tenth century, and the tradition is that a hunter of the name of Ramm, when engaged in the chase, had fastened his horse to a tree, when the animal, by pawing with his feet, scraped away the soil, and thereby discovered some minerals. Specimens of these were sent to the Emperor ORTHO, who immediately despatched expert miners to examine the district. The result was that mines were established, which still continue to be worked, and the oldest is named Rammelsberg, from the discoverer. JACOB estimates the whole Hartz, including the dominions of Hanover and Brunswick, with a small part belonging to Prussia, to have yielded, for some years prior to 1830, about sixty ounces of gold, and three hundred thousand ounces of silver annually.

From the times when the rich mines of Spain were last worked by the Romans, they seem to have been greatly neglected. CARDENNE, however, asserts that the mines of gold and silver which existed in that country were a great source of wealth to the Arabs. The mine of Zalamea, to the South of the river Guadiana in Andalusia, appears to have been worked in the middle ages. It is said to have contained silver without any mixture of lead, though near it was another mine yielding only lead; but the most important mines of Spain, and those which have attracted the greatest attention, from the earliest ages down to recent times, are the quicksilver mines at Almaden, and the silver mine at Guadalcanal. Of the latter Mr. BURR observes, that very minute and authentic records were preserved during the period it was worked in the sixteenth century, on account of the government. In these it is stated to have produced four hundred thousand two hundred and twenty-three

marcs of silver in the first few years after its discovery, and while worked by the state. After this period it passed into the hands of the Fucares, who are said to have obtained immense treasure from the mine previous to its being abandoned, and filling with water. It is only within the last twenty years, adds the same authority, that Spain has again become a silver-producing country, several very rich mines of that metal having been discovered since the recent revival of mining, which dates back only from 1825. In 1839 the celebrated mines of the Sierra Almagrera in the province of Almeria, were discovered, and they have ever since poured a large amount of silver annually into circulation. In 1843 another great discovery of silver was made—the mines of Hiendelencina in the province of Guadalajara, which have since been very productive; and, passing over recent and minor discoveries, Mr. BURR states that within the last few years the introduction of Mr. PATTISON's desilvering process—a process fully explained in the article LEAD—has been very general in the provinces of Murcia and Almeria. A large quantity of silver is thus annually obtained from the slightly argentiferous lead ores of the Sierra de Gador, and of Cartagena, not formerly extracted, but which now contributes to swell the production of this metal in Spain.

The silver mines of Norway and Sweden were long famous, but have latterly become less productive. The mine of Sahl, or Sala, is said to have been worked five hundred years ago. The silver mines of Kongsberg in Norway were scarcely known before 1623. In some years between 1710 and 1767 they yielded a large profit, but in others they were attended with heavy loss, and have frequently been suspended for long periods.

Although in ancient times Britain was celebrated only for its tin, and yielded but small quantities of the precious metals, yet not only does proof exist that gold was found to some extent, but STRABO states that silver mines were worked in this island, and TACITUS represents AGRICOLA, in his oration before the battle of the Grampian mountains, as reminding his soldiers of the riches in gold and silver which were to reward their valor. It is probable that these riches existed only in the historian's imagination—so far at least as they were to be found in a form available to the metallurgical skill which then existed. In modern times silver has been found in the British islands only in small quantities, except in connection with lead; and before the introduction of Mr. PATTISON's process, the trouble of its separation from that metal more than counter-balanced the profit. There are records, however, of silver mines in Cardiganshire, and also in the county of Tipperary in Ireland, both of which are said to have been worked to some extent during the reign of ELIZABETH. It is stated also that Sir JOHN ERSKINE was a proprietor of silver mines at Alva, near Stirling, which ceased to be worked in 1729, having been carried on for six years previously, under the direction of one PEEK, an Englishman; and in the reign of MARY STUART some silver mines were worked near Linlithgow. The produce must have been very trifling, and the profitable mining of either of the precious metals

was virtually a thing unknown in this country until the introduction of Mr. PATTISON's process rendered it advantageous to extract silver from lead; and as this metal is produced to a greater extent in Great Britain than in any other country in the world, the result is that, by virtue of the process above-mentioned, it is now actually entitled to no mean rank as a silver-producing country. The lead of some of the English mines, especially those of Cornwall, and also of the Isle of Man, contains considerable quantities of silver; and the reader will be surprised to learn that one of the highest authorities on this subject, Mr. ROBERT HUNT, has estimated that in 1852 the United Kingdom furnished no fewer than eight hundred thousand ounces of silver, worth, at five shillings an ounce, about two hundred thousand pounds, obtained from lead alone.

But the greatest impetus given to the supply of silver in what may be termed the modern era, arose from the discovery of America by COLUMBUS in 1492. It is true that up to the invasion of Mexico by CORTEZ, in 1519, gold alone had been found in America; or if any silver was procured, it seems to have been in small quantity. Thirty or forty years after that event, mines were in full work at Tasco, Zaltepeque, and Pachuca, but the use of mercury was not yet understood. The smelting of the ore was performed in small portable furnaces, or cylindrical tubes of clay, very broad and pierced with a great number of holes. In these the Indians placed layers of silver ore, galena, and charcoal, and a draught was created by the current of air which passed through the holes. Twenty years after the conquest of Mexico by CORTEZ, PIZARRO achieved that of Peru, and numerous mines yielding both gold and silver were soon opened in that country, but none equal in importance to the celebrated mines of the Cerro de Potosi, which were discovered accidentally in 1545. According to HERRERA, the discovery was made by an Indian hunter, DIEGO HUALCA, who, in pulling up a shrub, observed filaments of pure silver about the roots. On examination the mass was found to be enormous, and a very great part of the population was drawn to the spot and employed in extracting the metal. A city soon sprung up, though in a district of unusual sterility. The mountain was perforated on all sides, and the produce in a few of the first years exceeded anything that had been previously recorded in the mining history of the world.

The sensation created throughout Europe by the news of the discovery of the silver treasures of Potosi, can only be compared to the similar effect produced in recent times by the discovery of the auriferous deposits of California and Australia, which has been fully described in the article GOLD. The wealth of the new El Dorado was, however, grossly exaggerated. From reliable data it has been estimated, that between the year 1557, when the process of amalgamation was introduced, and the year 1578, the annual product of the Potosi mines did not exceed four hundred and forty thousand pounds sterling, which sinks into absolute insignificance compared with the vast amount of treasure now annually exported from California and Australia, without including the newly discovered and still comparatively unexplored deposits on the

banks of the Fraser River. On the whole, the greatest produce of gold and silver, even at that period, was from the Mexican mines, some of the richest of which were already in full activity, although the amount which they yielded was at that time much less than in the course of the two following centuries—the seventeenth and eighteenth—when quicksilver became more abundant, and was more extensively employed in the process of amalgamation. The chief increase of the precious metals between the years 1500 and 1600, was in silver from Mexico, where the production of Zacatecas, Guanajuato, and the other mining districts, had then greatly advanced. In the seventeenth century the silver mines of Yauricocha or Pasco, in the northern part of Peru, were first opened, and yielded a large amount of that metal. It is thus that though Potosi, which had at first produced the greatest quantity of silver, had declined, the product of the other parts of Peru so much increased as more than to compensate for that deficiency; and this increase, especially of silver, was greatly facilitated by the extension of the mines of mercury at Huancavelica.

The product of the precious metals from the American mines continued steadily to increase till 1809, when the convulsions commenced which terminated in the separation of the Spanish vice-royalties from the yoke of the mother country, and the erection of Mexico, Peru, and Chili into independent republics. During these troubles, which continued from 1809 to 1821, the produce of the mines greatly decreased, but has since been gradually augmenting.

The aggregate and relative amounts of silver obtained from different parts of the world, will be stated at the end of the article under the head of Statistics.

SOURCES.—As silver is of great use in the arts, not only for purposes of coinage, but also for services of plate for which it is peculiarly adapted, inasmuch as it is seldom attacked in the slightest degree by any of the substances used for food, so it occurs in great abundance in nature, and is largely disseminated both in the native state and alloyed with various other metals, occurring particularly in lead ores, as noticed under the article LEAD.

Native Silver is characterized by most of the properties of pure silver, but is always alloyed with a small quantity of other metals. It is generally dull at the surface, but exhibits, on being scratched, the pure white color characteristic of the metal. From its slight impurities, it is also less malleable and ductile than silver perfectly pure. It occurs sometimes crystallized in cubes and octahedrons; sometimes in thin leaves or in dendritical or arborescent shapes, resulting from minute crystals implanted upon each other; frequently also it is found in amorphous masses. It is met with chiefly in the primitive formations, as in granite and gneiss; more rarely in the argillaceous schists and grauwacke of the transition rocks, accompanied by quartz, carbonate and fluat of lime, sulphate of barytes, carbonate of iron, galena, *et cetera*. The principal localities in which it occurs native are—Kongsberg in Norway; Schlangenberg in Siberia; Freiberg, Schneeberg and Johanngeorgenstadt in Saxony; Joachimsthal, Przibram, and Ratiborzitz in Bohemia; Schemnitz in

Hungary; Kapnik and Felsőbanya in Transylvania; Andreasberg in the Hartz, Allemont in France; and, lastly, Mexico and Peru in America. In some of these localities it has been found occasionally in considerable masses. Thus, at Kongsberg, pieces have been extracted weighing from fifty to six hundred pounds; in America, at the end of the last century, lumps of two hundred to eight hundred pounds were obtained; and on one occasion a block of solid silver was discovered in the mine of Johanngeorgenstadt, which is said to have weighed nine or ten thousand pounds.

SULPHIDE OF SILVER.—*Glaserz* or *Silberglanz*, German—contains eighty-five to eighty-seven per cent of metallic silver. It is of a blackish dark-grey color, dull externally, but showing a metallic lustre when cut. It crystallizes in cubes or octahedrons, but is generally met with in the amorphous state. It is slightly malleable, almost as soft as lead, and is easily cut with a knife. It fuses readily in the flame of a blow-pipe, and even in a simple jet of gas, disengaging a slightly sulphurous odor, and ends by being reduced on the charcoal to metallic silver. It is met with in nature almost always combined with other sulphides, as those of copper and lead. This mineral is one of the richest and most abundant ores of silver; it forms a large proportion of that annually produced by the various foreign mines, as those of Saxony, Bohemia, and Hungary, and is particularly abundant in the mines of Guanajuato and Zacatecas in Mexico. Its composition, according to KLAPROTH, is—

	From Himmelfurst.	From Joachimsthal
Silver,	86.50	86.39
Sulphur,	13.50	13.61
	100.00	100.00

RED SILVER.—*Rothgültigerz*, German.—There are three species of this mineral:—1. *The antimonial sulphide of silver*, or a double sulphide of silver and antimony—an ore of a dark-red or reddish-black color, very nearly opaque, has a metallic lustre, and usually crystallizes in hexahedral prisms. Its constituents are—silver, from 56 to 62; antimony, from 16 to 20; sulphur, 11 to 14; and oxygen from 8 to 10. It is met with in almost all silver mines, but principally at Andreasberg in the Hartz, Freiberg in Saxony, Kongsberg in Norway, Schemnitz and Kremnitz in Hungary. 2. *Praistite*, or the double sulphide of silver and arsenic, which is of a clear red color, transparent, with a brilliant lustre, and contains sixty-four per cent of metallic silver. 3. *Myargyrite*, which differs from the antimonial sulphide only in containing one-third of the proportion of sulphide of silver.

BRITTLE SULPHIDE OF SILVER.—*Spradglaserz*, German—presents two varieties essentially distinct—

1. *Polybasite*, a combination of sulphide of silver, sulphide of copper, and sulphide of antimony or arsenic; has a semi-metallic lustre and an iron-grey color; seen by transmitted light, in thin scales, it presents a blood-red color; it contains 60.5 to 72.25 per cent of silver, and is found chiefly in the Saxon mines, and also in Mexico and Peru. 2. *Brittle Sulphide of Silver*, properly so called—German, *Schwarzgültigerz*—which is a combination of sulphide of silver with the sulphide of anti-

mony or arsenic; lustre slightly metallic; color iron-grey, and black when reduced to powder; is found associated with the preceding, as also in Hungary, Transylvania, *et cetera*. According to the investigations of ROSE and KLAPROTH, its composition is as follows—

	From Freyberg By Klaproth.	From Schemnitz By Rose.
Silver,.....	66.50	68.34
Copper and Arsenic,.....	00.50	0.64
Iron,.....	5.00	0.00
Antimony,.....	10.00	14.60
Sulphur,.....	12.00	16.42
Loss,.....	6.00	—
	100.00	100.00

Grey argentiferous Copper—*weissgültigerz*, German—a combination of sulphides of silver, copper, lead, and antimony; has a semi-metallic lustre, and a color intermediate between that of lead and steel. That which is found in the mines of Freiberg contains thirty to thirty-two per cent. of silver. The *graugültigerz* is a variety of grey copper much poorer in silver than the preceding.

Plumbo-argentiferous sulphide of bismuth—*wismuthbleierz*, German—is a brittle, leaden-grey mineral; it is a triple sulphide of bismuth, lead, and silver; contains fifteen per cent. of metallic silver. It is found at Schapbach in the Black Forest, but is a rare mineral.

Antimonial Silver—*speisglanz silber*, German—is a semi-metallic substance of a silver-white color, containing about seventy-seven parts of silver and twenty-three of antimony; it is found at Wolfach in the Black Forest, and in some of the Hartz mines, sometimes crystallized in rectangular prisms, but oftener in concrete masses.

Chloride of Silver.—*silberhornerz*, German, horn-silver—is semi-ductile and sufficiently soft to be cut with a knife; color, pearl-grey inclining to blue, and becoming brown in the air; has a vitreous lustre; is usually translucent; crystallizes in cubes. When pure it consists of silver 75.3, chlorine 24.7, and its composition is therefore represented by the formula Ag Cl .

This mineral, says PHILLIPS, which was formerly supposed to be of rare occurrence, constitutes one of the richest and most abundant ores of Chili, where it is frequently associated with native silver, apparently resulting from its decomposition. It also occurs in massive amorphous fragments in connection with sulphide of silver, but still more frequently in small cubical crystals disseminated in the ferruginous rock known in Chili and Peru under the names of *pacos* and *colorados*. Specimens of this mineral, although of comparatively rare occurrence in the European mines, have been obtained from Norway, Siberia, Saxony, the Hartz, and Cornwall.

Iodide of Silver is a rare mineral of a pale lemon-yellow color, with sometimes a tint of green. It was discovered by M. VAUQUELIN in the Mexican mines, but, from its rarity, is of no importance as an ore of silver. It is composed of silver 77.4, iodine 22.6.

Bromide of Silver was discovered by M. BERTHIER in the Mexican minerals, where it has since been found so abundantly in the district of Plataros, near Zaccatecas, that the ores there raised have received the name of *plata verde*, from the green color which it imparts to

them. According to BERTHIER, it is composed of silver 57.70, bromine 12.50.

Native Amalgam, or *argentale mercury*, has a very bright silver-white color, and is so soft as to be easily cut with a knife. It occurs both in distinct crystals and in irregular amorphous masses. It crystallizes in the regular octahedron or dodecahedron. This mineral is found in a great many different localities, but the finest specimens have been procured from Moschellandsberg in Bavaria. Its specific gravity is 14.1, and, according to KLAPROTH, it contains thirty-six per cent. of silver and sixty-four of mercury.

Another species of this substance, says PHILLIPS, forms one of the principal sources of silver in the rich mines of Arqueros, in the province of Coquimbo, Chili. From its malleability and general appearance this product was for a long time thought to be metallic silver. According to the analysis of Professor DOMEYKO, of the mining school of Coquimbo, this amalgam consists of silver 86.63, mercury 13.37, from which it appears to be composed of six equivalents of silver united to one of mercury, and its composition may therefore be represented by the formula $\text{Ag}_6 \text{Hg}$.

Argentiferous Galena.—The sulphide of lead, or galena, is almost always associated with a small quantity of silver in the state of sulphide, and this is the source of the silver obtained in the British Islands. It is regarded as extremely rich when it contains 0.005 of silver, and in many cases it may be extracted with advantage when only a tenth part of that proportion is present.

In general, and whatever may be their nature, minerals are regarded as rich which contain 0.005 of metallic silver.

PURE SILVER.—The silver of commerce is never perfectly pure, being always mixed with a certain proportion of copper and traces of other metals. A small quantity may be obtained pure by dissolving a piece of money or of plate in nitric acid, and adding a solution of chloride of sodium; a double decomposition occurs; the silver is thrown down in the form of an insoluble chloride, while the copper and any other metals that may be present remain in solution. One hundred parts of this chloride are, when separated and dried, mixed with seventy parts of chalk and four or five of carbon, and this mixture is introduced into a crucible and raised to a white heat. Carbonic oxide is disengaged, and chloride of calcium and metallic silver remain in the crucible.

To obtain the silver in a state of great purity, the chloride obtained by the double decomposition in the first instance ought to be repeatedly washed by decantation with boiling water, to be certain of dissolving the other metallic chlorides. Instead of chalk, the operation succeeds perfectly by mixing equal parts of carbonate of potassa or soda with three or four per cent. of charcoal in powder. But as the mixture fuses, the disengagement of gas produces, in this case, a tumescence which may project the matter out of the crucible. For this reason GAY-LUSSAC preferred the use of carbonate of lime, with which the reaction may be effected without fusion, reserving the temperature capable of melting the mixture for the time when, the

reaction being finished, no more gas can be disengaged. When the contents subside, the crucible is filled up with more of the mixture; and when the reaction is finished, the temperature is raised to a white heat; the chloride of calcium and the silver are melted, and the latter forms, on cooling, a button at the bottom of the crucible. The chloride of calcium, which lies above it, always contains a certain quantity of chloride of silver; and to separate the silver from the chloride recourse is had to the humid process. The chloride is first purified by washing, and then subjected to the action of a little sulphuric acid, and a plate of zinc purified by distillation. The reduction is effected rapidly, and the silver forms a grey, spongy, mass, which often floats on the top, because it is penetrated by hydrogen gas proceeding from the decomposition of the water. By stirring with a glass rod, after withdrawing the zinc plate, the hydrogen is separated from the spongy mass, which then falls to the bottom. The liquid is then decanted off, and its place supplied by water and a little sulphuric acid. This new treatment is necessary, for the spongy substance is a combination of silver with zinc, and not pure silver. Accordingly bubbles of hydrogen gas, proceeding from the solution of the zinc, are soon found to be disengaged abundantly. When this ceases, the powder is washed by decantation with boiling distilled water till the liquid is no longer rendered turbid by chloride of barium. In this way the silver is obtained pure, in a state of minute division.

Chemical Properties.—At ordinary temperatures silver is not acted upon by oxygen, but it is tarnished if exposed to an atmosphere containing very minute portions of sulphide of hydrogen, which is always present, to a greater or less extent, in the air of chambers heated by coal fires. When melted, however, in open vessels, it possesses the remarkable property of absorbing about twenty-two times its own bulk of oxygen, which in solidifying it disengages, producing, probably, that kind of metallic vegetation which takes place on the surface of the silver button when suddenly cooled in the cupel. It is not known whether there is chemical combination or merely mechanical absorption in this case; but BARRUEL considers the latter hypothesis by no means probable. The effects of this singular phenomenon, which has been already alluded to in Vol. II., page 284, in connection with the refining of gold, are best shown when the mass of metal is considerable, as, for example, about fifty or sixty pounds. They were carefully studied by GAY-LUSSAC and LUCAS, and are altogether so remarkable that a somewhat more minute account of them may not be unacceptable to the reader. After maintaining about the quantity of metal above-mentioned for a long time in a state of fusion, it is left to cool spontaneously, and begins to solidify at the surface. This process commences towards the edges, and advances towards the centre. The crust thus formed soon cracks, and very fluid silver escapes through the fissures, spreading itself over the surface in a thin layer. This first stage of the phenomenon appears due, not to a disengagement of gas, but rather to the expansion which results from a commencement of crystallization. Soon afterwards, as

the cooling proceeds, the gas in escaping begins to raise the solidified crust at several points, and produces a singular formation of miniature volcanic craters, through which a current of oxygen is disengaged, while lavas of melted silver stream over their edges. In the middle of each little crater the liquid mass is seen boiling violently. In proportion as the disengagement of gas proceeds, the height of these craters increases, in consequence of the solidification of the metal which flows over their sides; the greater part of them get partially choked up, whilst the gas escapes with a constantly increasing force, dragging along with it drops of melted silver, which it projects to a distance, and producing at each eruption small explosions, which succeed each other at very short intervals. The cones of eruption may ultimately attain a height of one and a half to two inches, with a diameter at the base of two to three inches; and for a quantity of fifty pounds of silver, the total duration of the *rochage*, as the process is termed in France, varies from thirty to forty-five minutes.

This phenomenon does not occur when the silver is alloyed with a small proportion of copper, gold, or lead; even one per cent. of copper prevents the absorption of oxygen on which it depends. That this is the cause of the phenomenon may be demonstrated on a smaller scale by heating to a white red in a crucible a considerable quantity of silver, and projecting upon it a little nitrate of potassa, which, by its decomposition, produces an atmosphere of oxygen. The crucible is then to be covered, and the heat continued for some time, after which the lid is removed and the vessel plunged into a tub of water, placing over it an inverted bell-glass filled with the same liquid; the oxygen which is disengaged is collected in the bell-glass, and may be measured. This experiment, says BARRUEL, is not without danger, for the oxygen may be disengaged all of a sudden, and thus produce a violent explosion.

When silver is subjected to a very high temperature, either by means of a burning lens, the flame of the oxyhydrogen blowpipe, or a powerful voltaic battery, it rapidly volatilizes, and burns with a greenish flame. In a state of fusion it may be crystallized, and in this case it assumes the cubical form.

Silver does not absorb the oxygen of the air when it is fused with the alkalis, and for this reason silver crucibles are used in laboratories for making analyses of silicates by means of the caustic alkalis, which would attack platinum ones. Chlorine, bromine, and iodine combine very well with silver, and of these three bodies iodine is that which has the greatest affinity for it. Of the acids, it is acted on most powerfully by nitric acid, which dissolves it in the cold; concentrated sulphuric acid requires heat to dissolve it. Hydrochloric acid attacks it only with difficulty, by leaving it a long time to digest; however, if the metal is in a very divided state, and the liquid be heated to ebullition, the action even of this acid is pretty rapid.

Silver readily combines with sulphur, and hence the fact already stated—the facility with which it is tarnished by contact with air containing even a very small proportion of sulphide of hydrogen. In this case its discoloration arises from the formation of a brown film of sulphide of silver. To clean articles so tar-

nished, the simplest method is to plunge them for some time into a solution of manganate of potassa—*chameleon mineral*—which is obtained by heating to redness a mixture of equal parts of potassa and binocide of manganese. In this operation the manganate is decomposed, and reacts on the sulphur of the sulphide of silver, which it oxidises and then dissolves. Oxygenated water, if convenient, may also be employed for the same purpose.

METALLURGY OF SILVER.—With reference to their metallurgical treatment, the minerals of silver are divided into four classes:—

1. Argentine ores, properly so called, and worked for the silver alone;

2. Ores of lead and silver;

3. Ores of copper and silver;

4. Ores of lead, copper, and silver.

The separation of silver from its ores is effected either by the method of amalgamation, or by a series of successive smeltings, which concentrate the silver in a certain quantity of lead, and the silver is afterwards separated by cupellation. The first of these processes consists essentially in bringing the silver ores, which have been previously pulverized and subjected to a special preparation, into intimate contact with metallic mercury; the silver is dissolved in the mercury, and the amalgam, being separated from the other matters by washing, is subjected to distillation; a residue is thus obtained. The advantage which this process presents over all others, is its great simplicity; but as any associated metals which may be present, such as copper and lead, are thereby lost, this method is usually employed only for ores which contain an insignificant proportion of these or other foreign metals. In the other processes the product obtained by successive roastings and smeltings is a quantity of *argentiferous lead* or *copper*, from which the silver remains to be separated. In the case of lead it is separated, as already stated, by cupellation; for copper, the mass must first be submitted to eliquation—an operation which consists in melting or *sweating out* the silver from the copper, and then cupelling with lead.

I. ORES WORKED FOR THE SILVER ALONE.—It has been stated that ores of this class, which do not contain an important proportion of other metals, are subjected to a process which consists essentially in forming an amalgam of the silver with mercury, and then subjecting the amalgam to distillation. This is the essential part of the process. Much of its success, however, depends on the manner in which it is conducted, and especially on certain preliminary operations which are required to bring the ore to that state of minute division in which it is most favourably circumstanced for causing the whole of the silver that is contained in it to combine with the mercury. There are two processes by amalgamation, the American or Mexican and the Saxon, which differ considerably from each other in this respect.

American process by amalgamation.—This method, invented in Mexico by BARTHOLOMEO DE MEDINA in

1557, is still practised in that country in all its primitive simplicity; and, perhaps, when the cheapness of labor, the poverty of the ores, the scarcity of fuel, and the deficiency even of water-power are considered, it could not be profitably superseded by any other. It will be found that its principal characteristics depend on these circumstances.

The ore, on being extracted from the mine, is placed in the hands of the *pepenadores*, men and women who break all the larger pieces with hammers, and after rejecting those in which their experience teaches them that no metallic particles are contained, and setting aside those which are very rich to be treated by the smelting process, they subject the rest to a process of crushing and pulverization, with a view to its direct treatment by amalgamation. The ores destined for this treatment are submitted in the first place to the action of the *ingenios* or stamping mills, which are either driven by mules, or, when water-power is at hand, by means of a small breast-wheel—Fig. 485. The long horizontal shaft fixed on the axis of the wheel is armed with five or six cams, placed at diffe-

Fig. 485.

rent situations round the shaft, so as to act in succession on the projecting teeth of the upright pestles or stampers, each of which weighs two hundred pounds, and works in a corresponding oblong mortar of stone or wood. It is estimated that a battery of eight of these stampers, is capable of reducing to powder three thousand five hundred pounds of ore in twenty-four hours.

The powder thus obtained not being sufficiently fine for the purpose of amalgamation, it is transferred from the stamps or *morteros* to be reduced to an impalpable slime or mud in the crushing mills or *arrastres*, represented in Fig. 486, into each of which a little water is introduced. These mills are commonly worked by mules, which turn a vertical shaft armed with two cross-bars. The grinding stones, as well as the sides and bottom of the mill itself, are composed of granite, four blocks of which revolve in each crushing mill, one attached to each of the arms. They are usually placed in a covered shed or gallery, as shown in the figure, which represents the *arrastres* of the *hacienda* or metallurgic works of Salgado, near Guanajuato. These

contain thirty-six dry stampers, also worked by mules, and forty-two crushing mills in which water is used. Each of the latter reduces to a fine impalpable metal-

liferous mud six hundred pounds of powder in twenty-four hours. The mules are changed every six hours. This operation is considered of great importance, for

Fig 486.

the subsequent amalgamation is so much the more complete, and the loss in mercury less considerable, in proportion as the ore is reduced to a more minute state of division.

The ore thus ground into a fine paste is termed

Fig. 487.

lama, and is conveyed into pits of three to six feet in depth, where it is allowed to dry in the sun till it acquires a certain consistence. It is then carried to the *patio* or amalgamation floor—Fig. 487—which is a flat space open to the sky, and surrounded by a stone wall. At Zaccatecas the *patio* is rectangular, three hundred and twelve feet in length by two hundred and forty in breadth, and capable of containing twenty-four flat circular heaps of *lama*, each about fifty feet in

diameter and seven inches deep, arranged in four rows. These heaps are termed *tortas*. A small space is usually reserved at one corner for the purpose of performing assays on the ore, with the view of determining beforehand the proportion of mercury that may be necessary to incorporate with each heap.

At Zaccatecas the *tortas* are formed in the following manner:—In the first instance a space of the requisite size is marked out and inclosed by a number of rough planks, which are propped in their places by large stones. About one hundred and fifty bushels of crude or impure sea-salt are then introduced into this inclosed space, and over this about six hundred metrical quintals of the *lama* or ore in a state of fine paste. The salt and *lama* are then well mixed by turning with shovels and treading with mules, after which the mixture is left at rest during the remainder of the day. On the morrow, after about an hour's further treading with mules, the *magistral*, or roasted and pulverized copper ore—a mineral containing ten per cent. sulphate of copper, and as much sulphate of iron—is added in greater or less quantity, according to the richness of the argentiferous ore and the season of the year; in summer, for example, and with the richer ores, about seven hundred and fifty pounds to the *torta*, and in winter only half that quantity; for it is stated as a singular fact that in summer the mixture cools and requires more warmth, while in winter it acquires of itself additional heat. The larger proportion is for minerals containing 0.0015 of metallic silver. When the operation proceeds too rapidly, arising from the presence of too much *magistral*, which would occasion

a greater loss in mercury, the remedy is to add a certain quantity of lime, which serves to cool the lama.

When the magistral has been introduced, the treading out is continued for five or six hours by means of six mules. When the whole has been well mixed, the process of amalgamation is commenced by adding a certain quantity of quicksilver, which is sprinkled over the heap by straining it through a bag of coarse cloth. The treading by mules is then continued, and the whole is turned over for some hours with wooden shovels. This operation is repeated for several days, until the amalgamator ascertains by examination that all of the mercury is taken up. He then adds a second and sometimes a third charge, repeating on each occasion the same treatment. When the last charge has been added, the mixture is again thoroughly trodden, and the mass is then removed by the laborers on handbarrows to the *lavaderos*, where the amalgam is separated from the earthy matters by washing.

To judge of the progress of the amalgamation from time to time, the amalgamator uses a small black earthenware basin, flat and round, or somewhat similar in form to that represented in Vol. II., Fig. 221, page 272. In this dish he puts a little of the lama or paste which is under the process of amalgamation, and holding the dish inclined and half-immersed in the water, he gives it a rotatory movement in a plane perpendicular to its axis, so that there is formed in the submerged part of the basin a circular current of water which retains the sand in the centre, while the heavy or metallic grains arrange themselves around the circumference according to their specific gravities, and there the amalgam is observed in small spangles. Usually eight parts of mercury are added for one part by weight of silver contained in the ore. Thus, at Zaccatecas, for an ore which is presumed to contain 0.001625 of silver—and this is the average proportion—there is added to the torta, which is estimated to contain about two hundred pounds of silver, on the first occasion nine hundred pounds of mercury; on the second, three hundred pounds; and on the third and last, four hundred and twenty pounds, making a total of one thousand six hundred and twenty pounds of quicksilver. The entire duration of the amalgamation is twelve to fifteen days in summer, and twenty to twenty-five in winter. This is less than a third of the time required at some other Mexican mines, which evidently arises from the small elevation given to the tortas, and the consequent exposure of a large surface to the action of the solar rays.

The next operation is the washing of the amalgamated ore, for the purpose of removing the earthy matters, and of thereby obtaining the amalgam or mixture of silver and mercury in a separate form. This operation is performed in *lavaderos*, or washing vats, which are circular in form, and solidly built in masonry, each about eight feet deep and nine in diameter. A horizontal toothed wheel, mounted on a shaft worked by mules, communicates, through the intervention of another toothed wheel, a movement of rotation to a vertical shaft placed in the middle of the vat, and armed at its lower part with four agitators consisting of cross

beams, from which rise long wooden teeth to the height of five feet. A small stream of water continually flows into the vats from a tank on a higher level. Under the action of the agitators the lighter earthy matter is kept afloat, while the heavier amalgam sinks to the bottom, and from time to time the former is allowed to flow out into a second similar apparatus, where it is subjected to a second washing, and then allowed to run away. An entire torta of amalgamated ore may thus be passed through one vat in twelve hours.

The liquid amalgam obtained in this manner is then strained through a leathern bag, the bottom of which is formed of strong canvass or thick flannel. The uncombined mercury is thus squeezed out, carrying along with it a small quantity of silver, which is not lost, as the same mercury is employed in the next amalgamating operation, while there remains in the bag a mass of semi-solid amalgam, which is submitted to distillation to obtain the silver. For this purpose it is moulded into wedge-shaped masses, each about thirty pounds in weight, which are arranged in a circle in what is called the *burning house*, to the number of eleven, on a solid plate of cast-iron having a hole in its centre. Over this row of wedges several others are built, and the whole pile is covered with a large iron bell called a *capellina*, which is lowered down upon it by means of pulleys, and carefully luted at the bottom to the iron plate with a mixture of ashes, crude salt, and lama. A loose wall of fire-bricks is then built round the capellina, leaving an interval about a foot in width, which is kept filled with burning charcoal all night; and after the heat has been applied about twenty hours the bricks and ashes are removed and the capellina hoisted up. The silver is then found in a solid mass, the mercury having passed off in vapor through a pipe fixed to the opening or hole in the ground plate, by which it is conveyed into a cistern filled with water, and there almost all condensed. The silver, which remains on the plate in solid pieces, is weighed, and is then usually remelted in reverberatory furnaces, and cast into ingots or bars, each about eighty or ninety pounds in weight. Latterly, at some establishments cylindrical retorts of cast-iron have been introduced for distilling the amalgam. The loss in mercury is usually about one and a half per cent. of the weight of silver obtained.

The rationale of the process of amalgamation, as above described, may be explained as follows:—In America the silver exists in the ores, partly in the native state, partly as a chloride, and partly as a simple or multiple sulphide. The copper pyrites which is added reacts on the chloride of sodium employed, producing sulphate of soda and bichloride of copper; the latter acts as an energetic chloridizing agent on the sulphide of silver in the ore, which it changes into chloride of silver, passing at the same time itself into the state of protochloride. The chloride of silver is in its turn reduced by a part of the mercury added, forming with that part protochloride of mercury, and with the other an amalgam of silver. It is the protochloride of mercury so formed that is carried away by the waters in the process of washing, and constitutes almost the whole of the loss in mercury. The

chloride employed serves not only to transform the sulphate of copper into deutochloride, but likewise to dissolve the chloride of silver, and thus to facilitate considerably its reduction by the mercury.

On an average the American ores are very poor, and do not contain more than 0.00150 to 0.00160 of silver. It is their immense quantity, and not their superior richness, that explains the large production of the silver mines of America. The most celebrated are those of Pasco, Cerro de Bambon, Chota, and Huantajaya in Peru; Zaccatecas, Guanaxuato, Valenciana, and Veta-grande in Mexico. Pasco produces annually one hundred thousand to one hundred and fifty thousand pounds of silver; Huantajaya fifty thousand pounds; Zaccatecas three hundred thousand pounds; Guanaxuato two hundred thousand pounds; Valenciana one hundred and fifty thousand pounds. It is estimated that five-sevenths of the silver produced in America is obtained by amalgamation, and only two-sevenths by smelting the ores.

Saxon Process by Amalgamation.—It was only at the end of the last century that the method of treating silver ores by amalgamation was introduced into Europe. Here the circumstances are different to those in Mexico and Peru; fuel is cheaper, mechanical moving power is abundant; manual labor is more expensive; it is therefore important to replace the latter as far as possible by the former two, and this principle will explain the chief points in which the European process differs from the American. These points of difference will appear from the following account of the method by amalgamation, which is practised at the Halsbrücke works, near Freiberg, in Saxony, the most complete establishment of the kind in Europe.

In these works no ores which contain more than seven per cent. of lead, or ore of copper, are submitted to amalgamation, because beyond that point the lead entering into the amalgam would render it very impure, while making the operation itself more difficult, and the copper would be entirely lost. The most usual constituents of the ores are sulphur, silver, antimonial silver, bismuth, sulphides of arsenic, of copper, iron, lead, zinc, *et cetera*, with several earthy minerals. Ores of different qualities are sorted together in such a way that the mixture may contain an average of about four ounces of silver per one hundred pounds of ore. It is necessary, also, that they shall contain a certain proportion of sulphur, to decompose sufficient chloride of sodium in the roasting to cause as much chlorine to be disengaged as shall convert the whole of the silver into a chloride. Accordingly, ores poor in sulphur are mixed with those that are richer, and generally about thirty per cent. of iron pyrites is added. When the whole has been well pulverized in a stamping mill, about one-tenth of its weight of salt is added, and the mixture is then roasted in a reverberatory furnace, the floor of which is elliptical, and is about six feet in length by eight in breadth; the height of the vault in the centre is about eighteen inches. The furnace is charged with three and a half to four hundredweights of the prepared ground ore, which is first dried at a low heat with incessant turning over; the fire is then gradually raised. At first vapor of water is disengaged, then

dense white fumes of arsenious acid and oxide of antimony, which deposit themselves in the condensing chambers above; after this the ignition of the iron pyrites becomes obvious by the appearance of a bluish flame and a strong odor of sulphurous acid. When this smell has passed away the chlorination is commenced by raising the temperature to a bright red, and maintaining it at that point till no more gas is disengaged; this requires about three-quarters of an hour, so that a charge is passed through the furnace every four hours. During the first part of the operation, or the roasting properly so called, the arsenic and antimony are separated, and the sulphides of iron and copper are converted into a basic sulphate of sesquioxide of iron and subsulphate of copper. These sulphates, in the second part of the process, or the chlorination, react in their turn on the chloride of sodium, producing sulphate of soda, protochlorides of iron and copper, and chlorine, which combines in the nascent state with the silver contained in the ore, thereby converting it into a chloride. Here it is the chloride of iron which principally acts as the chloridizing agent, whereas in the American process it is the chloride of copper. At the Halsbrücke works there are fourteen roasting furnaces, in each of which about five tons of ore are operated upon weekly; and the condensing chambers or soot vaults yield in the aggregate, during the same time, from four to five tons of ore-dust, containing about sixteen pounds, or 0.00125 to 0.00150 of silver. This dust is treated separately in the same manner as the crude or unroasted ore. The fuel of the first fire is pit-coal; of the finishing one fir-wood. Of the former one hundred and fifteen cubic feet, and of the latter two hundred and ninety, are upon an average consumed for every five tons of ore. The service of a roasting furnace requires two workmen per twenty-four hours of work.

The roasted ore is thrown on a grating inclined at an angle of 45°, and having sixteen apertures to the square inch. That which passes through falls on a sieve or riddle about eight feet long by eighteen inches in width; it is inclined at an angle of 6°, and, in the upper part, has eighty apertures to the square inch, but only fifty in the lower. Three degrees of fineness are thus obtained—the *coarse*, which remains on the grating and the riddle; the *fine*, which passes through the upper part of the riddle; and the *middling*, which passes to the lower part. On the average the proportions obtained are twenty-nine parts of fine, one of middling, and one and a half of coarse or large grains. The latter is broken with a hand-hammer; it is then crushed, along with the middling size, under granite millstones, and afterwards subjected to a second roasting with two per cent. of chloride of sodium; but in this case the operation lasts only two hours instead of four as formerly. The fine is ground in a dry state between granite millstones. The top stones or runners make one hundred and twenty to one hundred and forty turns per minute; they are radiated like those of meal mills; the grooves have a depth of about one-fifth of an inch, and require to be dressed or renewed every three or four days. When they are first put up they are about two and a half feet in diameter, with a thick-

ness of about twenty inches; and when this thickness is reduced one-half, they are used for the lower or bed stones. It is estimated that from two to three horsepower is required for each mill. There are in all ten pair of stones, and each of them grinds per hour from one hundred to one hundred and fifty pounds of roasted ore, besides which there remains on the bolter twelve to fifteen per cent. of coarse material, which must be passed a second time between the stones. The service of two pair of stones requires two workmen per twenty-four hours of work.

The amalgamation is performed in casks firmly hooped with iron, and each about two feet ten inches

Fig. 488.

long by two feet eight inches in internal diameter. There are twenty of them, arranged in four rows, and turning on horizontal axes. Figs. 488 and 489 will give an idea of this arrangement. Attached to the end of each cask, *c, c*, is a toothed wheel, *m m*, which engages another toothed wheel, *M*, mounted on a shaft,

Fig. 489.

s, which is driven by water-power. Each of the casks has an opening, *r r*, about four inches in diameter, and securely closed by an iron or wooden screw stopple during the amalgamation. The roasted ore is charged into hoppers, *D, D*, which are prolonged downwards by conical tubes, *d, d*, and leather hose, *e e*. The latter are introduced, during the charging of the casks, into the openings, *r r*, and then turned upward as one of them is shown in the figure. Above each cask is a vessel, *E*, for containing the exact amount of water

required for each charge, and these are also fitted with flexible tubes and stopcocks for allowing the water to pass as required. The bearings of the wheels, *m m*, mounted at one end of each of the barrels, and through which they receive their movement from the wheel, *M*, are supported on slides which move to and fro upon the bars, *f*, and the wheels can therefore be disengaged at pleasure. The charge is commenced by introducing into the barrels the water from the vessels, *E*, each of which contains thirty-three gallons, and the whole of this is transferred into the barrels; the roasted ore, to the amount of ten hundred-weights for each, is then introduced, and lastly there is added from eighty to one hundred pounds of iron in pieces about one and a half inch square by three-eighths thick. The stopples are then screwed in, and the casks are thrown into gear, and made to revolve slowly for about an hour and a half at the rate of fourteen to fifteen turns in the minute. During this stage, the chloride of silver dissolved in the alkaline chloride is decomposed by the fragments of iron, producing chloride of iron and metallic silver. It is very important that the roasting should have been carried far enough to decompose all the chloride of copper; for if not so, the latter would be equally reduced by the iron to the metallic state, and would subsequently pass into the amalgam, rendering it very impure. At the end of an hour and a half the barrels are stopped, and five hundred and fifty pounds of mercury introduced into each, by means of pipes connected with the tube *g*, which communicates with a large graduated iron reservoir. The barrels are then put in motion again, with a speed of twenty to twenty-two revolutions per minute, and this is continued for nineteen hours without intermission, except for a short period at the end of every four hours to examine whether the paste has the proper consistence, and to judge of the progress of the operation. The reaction is facilitated by the elevation of temperature which is observable in the contents of the barrels, and which is greater in proportion as the velocity of rotation is more considerable. The higher the temperature the more completely will the residues be exhausted, but the greater will be the loss, in the subsequent washings, of very minutely-divided mercury, which it will then be impossible to recover. There is therefore a proper medium, which has been determined by experience to correspond to about 90°.

The amalgamation being now considered as terminated, the barrels are nearly filled with water, and are made to revolve during two hours with a speed of eight or nine turns per minute, to collect the amalgam. The motion is then stopped, and the process of discharging them is proceeded with. For this purpose the conical bungs, by which they were hermetically sealed during the amalgamation, are removed, and a leathern tube fitted with an iron stopcock is inserted into each aperture; the barrels are then reversed, so that the apertures are turned downward, and the amalgam is made to fall along the sluice, *h*, into the gutter, *i*, which conducts it to a general reservoir. The barrels are then turned up to adjust to them hollow stoppers fitted with wire-grating; and in reversing them again the slimy residue falls into the canal, *o*, which

conducts them to the washing vats, while the pieces of iron retained by the grating remain in the barrels. Altogether each operation lasts twenty-four hours. About two pounds of iron are consumed in each barrel at one operation, and about thirty pounds are added every fifteen days.

The amalgam obtained is strained by hand labor through a flannel bag of a conical form; the mercury which passes through contains at the utmost 0.00004 of silver, and is passed back into the amalgamation barrels. The solid amalgam, which remains in the bag, contains, according to KERSTEN'S analysis:—

Mercury, ..	84.20
Silver,	11.00
Copper,	3.50
Antimony, zinc, and lead,	1.00
Sulphur,	traces.
Loss,	0.30
	100.00

Distilling the Amalgam.—The mercury is separated from the silver by distillation. For this purpose the amalgam is placed in flat iron dishes, under a bell-apparatus. Fig. 490 represents the four bells employed at the Halsbrücké establishment; *m, m, m, m* are wooden drawers, sliding in grooves upon the bases *q q*; and each of which contains an open box or basin, *o o*, of cast-iron. In these basins are placed vertical iron rods, *a a*, resembling candelabra, resting upon three

Fig. 490.

feet, and each supporting five flat iron dishes, formed with holes in the centre, whereby they are fitted upon the iron rods, three inches apart, each plate being successively larger than the one above it. About sixty pounds of amalgam are put into each dish, and the whole is covered with a cast-iron bell, *b b*, which is raised and lowered by means of pulleys. When the bells have been let down into their place, the aperture through which they descend is covered with an iron plate, *r*, and the open space, *s s*, which forms the stove, is closed in front with a door, *c*, the edges of which are carefully luted. The boxes, *m*, and basins, *o*, are filled with water, which must be continually renewed through pipes in the sides of the boxes, so that the iron basins may always be kept partially immersed, and as cool as possible. The fuel is then placed in the vacant spaces, *s s*, round the upper part of the bells; and the doors, *c*, being closed and luted, the fire is fed gradually, first with turf and then with charcoal, in such way that it does not attain its maximum heat until about eight hours have elapsed, after which the fire is allowed to decline gradually. The

management of the fire is a point of the greatest importance, and requires the most careful attention, for if the temperature be not raised very cautiously, there is much risk of the bell breaking, and also of a part of the silver being carried over mechanically by the mercury in volatilizing; on the other hand, if the temperature be not sufficiently elevated, there will remain in the silver a greater or less amount of the mercury, which will be completely lost in the refining.

Each distilling operation lasts twelve hours, and the product is about forty-five pounds of plate or *teller* silver from each bell. The teller silver contains only about seventy-five per cent. of fine silver, the remainder being chiefly copper; it is melted in an open iron crucible, and cast into ingots—a process by which some of the impurities are removed, and the ingots contain about eighty per cent. of fine silver.

The earthy residuum of the twenty barrels in which the amalgamation was performed is run into five circular tanks, each about five feet in depth, with a diameter of five feet at the top and three at the bottom; these are filled up with water, and in the side of each there are four orifices, arranged one over the other, at a distance of about five inches from each other. In the middle of each tank is a vertical axis, carrying horizontal arms, which are made to revolve during twenty to twenty-two hours at the rate of twelve to fourteen turns per minute; and while this agitating process is going on, the supernatant liquid, containing the lighter earthy impurities, is allowed to flow out, twice by the highest orifice, twice by the second, and once by the third or lowest, taking care to fill up the tanks with water after each partial discharge. The amalgam itself is drawn out by the lowest orifice only once a-week; it is very impure, and after being fused yields an alloy which contains only twenty-five to sixty-five per cent. of fine silver. This product might be refined by fusing it with a little saltpetre and borax, but it is sent by preference to the Mint, where it is alloyed with the fine silver which is obtained from the cupellation of lead. The amount of the residues, which are finally rejected as useless, rises to eighty per cent. of the weight of the crude ore, and their contents in fine silver varies from 0.00008 to 0.00016. The waters which proceed from the washing of the amalgamation barrels are purified by deposition, and then concentrated and crystallized in leaden pans; the product is a quantity of impure sulphate of soda, which is februated by a second crystallization. The mother-water, or that portion of the liquid which refuses to crystallize, is concentrated by milk of lime; and the product thus obtained, which is termed in German *dünge salz*, is employed in the country with much advantage as a manure; it is composed, according to M. LAMPADIUS, of—

Hydrated gypsum,	68.7
Chloride of sodium,	7.4
Carbonate of potassa,	5.3
Hydrates of manganese and iron,	12.9
Clay, sand, and loss,	5.7
	100.0

The total loss in silver varies from five to nine per cent. of the quantity contained in the ore; the loss in

The following table exhibits the effect of PATTISON'S process on one thousand parts of workable lead containing different proportions of silver:—

Workable lead submitted to one crystallization.		Rich lead.		Lead middling rich, to be recrystallized with the workable lead.	Poor lead.		Proportion between the content in silver of the rich lead and that of the poor lead.
Weight.	Content in silver.	Weight.	Content in silver.	Weight.	Weight.	Content in silver.	
1000	0.001606	136	0.003800	125	739	0.001200	3.17

1000	0.000030	100	0.000130	125	650	0.000020	6.50

It will be seen that the concentration of the silver by this process is all the more complete, in proportion as the lead subjected to the operation is poorer in that precious metal; hence, it is particularly applicable to the leads of England and Spain, but not to rich leads. Neither can it be applied with advantage to leads which are both poor and impure, because by cupellation the advantage is gained of separating the impurities in the abstrichs, so that litharges are obtained which are commercially valuable in themselves, or which, if subjected to reduction, yield a lead of superior quality.

The silver obtained from the cupelling furnace represented in Figs. 492 and 493, as well as the rich lead concentrated by PATTISON'S process, still requires further purification, and for this purpose it is subjected in both cases to cupellation on a small scale, with a cupel or test made of bone-ash. Figs. 494 and 495

Fig. 494.

Fig. 495.

represent the refining furnace employed for this purpose at Friedrichshütte; *c* is the fire-door; *d* the grate; *e*, door for charging the rich lead into the cupel; *f*, elliptical cupel of bone-ash, the longer axis of which is about sixteen inches, and the smaller axis ten inches; this cupel is movable, and rests upon two iron bars, *g g*, over which are tiles, *h h*, for adjusting the surface

of the cupel at any desired level; *i*, flue leading to a chimney about eighteen feet in height. About one hundred and ten to one hundred and thirty pounds of rich lead or impure silver constitute one charge of the cupel; and the silver obtained from a previous cupellation on the large scale, yields about ninety-four per cent. of fine silver.

III. ORES OF COPPER AND SILVER.—In smelting argentiferous copper ores, the principal object in view is to obtain the baser metal in that state in which it is termed *black copper*; and when this metal contains not less than 0.003 of silver it is deemed sufficiently rich to be submitted to the process of liquation or sweating. This process has been briefly described in the article COPPER, Vol. I., pages 522 and 523; but some additional details will now be necessary. In the first place, the black copper is fused with a certain quantity of poor lead, and the alloy so formed is cast into cakes or discs; these are then submitted to a carefully graduated heat, which causes the lead to melt or sweat out, carrying along with it the greater portion of the silver, which has a stronger affinity for that metal than for the copper. This is the process termed liquation or eliquation. It has been found by experience that, with a view to diminish as much as possible the loss in copper and in lead, the most suitable proportion between the quantities of lead and copper in the prepared discs, is that of eleven parts of the former metal to three of the latter; and that, to extract the silver sufficiently, it is necessary to employ at least four hundred and eighty parts of lead for one part of silver contained in the black copper.

When the black copper is only slightly argentiferous, the poor lead, which has served for a first liquation, is not sufficiently rich to bear advantageously the expenses of cupellation; in that case it is used a second time for extracting the silver from a fresh quantity of black copper. By this means the content of silver in the alloy is nearly doubled, and then it is suitable for being submitted to cupellation.

Lastly, when the black copper is very rich, the process is commenced by subjecting it to a first liquation with workable lead, the products of which are a rich lead for cupelling, and a middling rich black copper; the latter is then submitted to a second liquation with poor lead, which yields cupreous residues very poor in silver, to be treated for rosette copper, and moderately

rich workable lead, which is passed back into the rich liquation process.

The content in silver of the black argentiferous coppers of Mansfeld, which are treated at the liquation works of Hettstœdt, where both the lead and fuel are very high in price, averages 0·00520. The fusing and casting of the liquation discs is performed in a cupola furnace. Each campaign lasts thirty hours, during which time two hundred discs are cast, each weighing about three hundred and eighty pounds, and measuring about two feet in diameter by three inches in thickness. For one thousand pounds of black copper, the proportion of poor lead added is four thousand four hundred pounds. The liquation furnace, with the discs arranged in their place, is represented in Figs. 333 and 334, Vol. I., at the pages above referred to. When the lead, carrying most of the silver along with it, has been melted out, the deformed discs which remain are termed *carcas*. When the heat has been well regulated, all the lead which separates by liquation contains a uniform admixture of copper to the amount of between two and three per cent.

The *carcas*—German, *kienstœcke*—still contain twenty-five per cent. of lead, and, to free them from this, they are subjected to a new liquation, which is termed in French, *ressuage*; German, *darren*. For this purpose the *carcas* are accumulated to the extent of fifteen to twenty thousand pounds weight, in a vaulted chamber, on a series of low parallel walls, between which a wood fire is kept up. In the walls of the chamber are a number of draught holes communicating with a chimney. In front this oven is closed by an iron door lined with clay, but leaving an opening at the bottom for the purpose of introducing the fuel and allowing air to enter. A red heat is kept up during fourteen to fifteen hours; the lead which was still retained by the *carcas* soon begins to run, and becomes in great part oxidised. It falls into the galleries in the middle of the fuel, which have a gentle slope, so that both the lead and its oxide, more or less charged with copper, flow into a basin of water which is placed on the floor of a chamber in front of the oven. The fire is allowed to go out when the scoriæ assume a strong red tinge, which denotes the presence of copper. The residues, which are termed *torrefied carcas*, are then withdrawn, while still at a red heat, and thrown into water to separate the scaly crust of oxide with which they are covered, and which is afterwards separated more completely by means of a pointed hammer. As a general rule, one hundred pounds of *carcas* yield sixty to eighty pounds of torrefied *carcas*, and twenty-five to forty of scoriæ and oxidised debris.

The torrefied *carcas* are refined for rosette copper; they still contain ten per cent. of lead, and yield seventy to seventy-five per cent. of rosette copper.

The scoriæ and refuse of all the preceding operations are fused with the litharges and the residues from the cupellation of the workable lead obtained in the process of liquation; the product is a cupreous lead, which is cast into cakes or discs, and these in their turn are subjected to the series of operations which have just been described. The lead proceeding from the new liquation is, however, poor in silver, and is therefore enriched

by using it for the liquation of the black copper before passing it into the cupel.

In this series of operations, there is lost about ten to twelve per cent. of the lead employed, that is to say, forty to fifty per cent. of the weight of the black copper, or at least sixty to eighty pounds for every pound of cupel silver obtained. The loss in silver usually exceeds twenty-five per cent., regarding that silver as lost which remains in the copper. The loss in copper is five to six per cent. The *carcas* are very difficult to refine, and never yield copper of the first quality.

These results show how imperfect is this method; and hence, in the great metallurgical centres, the method now preferred is to separate the silver from the copper, either by the amalgamation of the matts or by that of the black copper. These operations are effected in a manner analogous to the Saxon amalgamation process, which has been already described, so that it will be only necessary to indicate briefly the special circumstances resulting from the nature of the materials submitted to the operation.

The amalgamation of the argentiferous black copper is practised at Schmölnitz in Hungary; it contains 0·0040 of silver. The principal difficulty to be overcome is the pulverization of the black copper: to effect this, it is heated to redness on the sole of a reverberatory furnace, and at this temperature it is placed under the pestles of a stamping machine. The matter thus crushed and broken is passed through a sieve; the finer portion is ground to a flour under iron mill-stones, the coarse is reheated and passed again under the stampers. The reduction of the chloride of silver is performed by means of copper balls, so as not to precipitate the copper from the chloride and thus render the amalgam impure, but then the loss in mercury is considerable; in certain cases it would be advantageous to saturate the liquor with lime, and to replace the copper balls by iron, which would diminish the loss in mercury. The residues of the amalgamation are remelted for black copper; their content in silver does not exceed 0·00008, and the loss in that metal is only five per cent.; the loss in mercury is 2·5 lbs per thousand lbs of black copper, or from 0·30 to 0·35 of the weight of the silver. The expenses of amalgamation do not rise to one-fourth part of those attending liquation, and the copper obtained from the smelting of the residues is of superior quality.

The amalgamation of the argentiferous matts of copper is practised at Mansfeld. The matt subjected to amalgamation at that establishment contains about fifty per cent. of copper, and 0·0025 of silver. After pulverizing the matt, it is submitted in a reverberatory furnace to a preparatory roasting, to expel the excess of sulphur; it is afterwards reduced to a thin paste with a dilute solution of sea-salt and twelve per cent. of slacked lime, which serves to saturate the sulphuric acid. The paste thus obtained is dried, ground, then roasted a second time; this is, properly speaking, the chloridation. The reduction of the chloride of silver is effected by means of iron. The residues of amalgamation are mixed, still in a moist state, with twelve to thirteen per cent. of clay, and moulded into small bricks, which are dried in a kiln, and reduced in a

furnace to black copper by adding, to form the smelting bed, twelve to thirteen per cent. of quartz, 1.5 to 2.5 per cent. of fluor spar, and thirty-two to forty per cent. of the slag from the smelting of the crude ore. The loss is eleven to twelve per cent. of the silver contained in the matts, about three-fourths of this amount remaining in the black copper, which contains 0.00046; the loss in mercury is 0.8 of a pound per thousand pounds of matt, or 1.6 pounds per thousand pounds of black copper, that is to say, about 0.35 of the weight of the silver extracted. The loss in copper is less than by liquation, and the metal is of excellent quality.

Instead of employing the different processes which have just been described, the ores of argentiferous copper might be treated in the humid way, in a manner analogous to that which is practised at Linz on the banks of the Rhine, and at Stadtberg in Westphalia, for the treatment of carbonated copper ores too poor to be treated by the ordinary processes. This method consists in treating these ores with sulphuric acid. It is impossible to submit to the direct action of this acid either calcareous or pyritous ores—the former, because a sulphate of lime would be formed which would cover or surround the copper with a paste, so as to be acted upon with difficulty; the latter, because it would scarcely dissolve in the acid. It would be necessary therefore, in these cases, to separate the gangues by smelting the crude ores, which would give them in the form of matts; and these might be roasted with a small quantity of saltpetre in furnaces, or retorts embedded in masonry, and supplied with an artificial blast. A little small wood would be sufficient to commence the heating, as the combustion of the sulphur would afterwards develop the heat necessary for the roasting. The gases proceeding from the retorts should be made to arrive, along with a current of steam produced by a separate boiler, under and around cases filled with roasted and pulverized matts; by the reaction of the steam and the gases from the retorts, sulphuric acid would be formed, which would dissolve the roasted matts; the latter might be exposed beforehand, in heaps, to the simultaneous action of the atmospheric agents and water, to transform the undecomposed sulphides into soluble sulphates, which might be removed by washing. In like manner, if the roasting of the matts did not furnish a sufficient quantity of sulphuric acid, an additional quantity might be procured by subjecting iron pyrites to the same process. A liquor would thus be obtained, containing the iron, copper, and silver of the matts; and of these the silver might be precipitated at once by metallic copper, then the copper by iron. It might be desirable, for the purpose of diminishing the consumption of copper, to almost neutralize the liquor in the first place by means of lime, and then to separate the sulphate of lime by decantation, which would be attended with no other inconvenience than impairing a little the purity of the precipitates. The silver precipitate might be purified by fusing it with a little nitre and borax; the copper could be refined for rosette copper; and lastly, the sulphate of iron, or green vitriol, might be crystallized for the market, or if dried and then slightly torrefied, it might be used for the manufacture of fuming sulphuric acid.

As regards the argentiferous black copper, it might be dissolved directly in the sulphuric acid, and the silver afterwards precipitated by metallic copper, as is practised in the mints.

IV. ORES OF LEAD, COPPER, AND SILVER.—The treatment of these ores is perhaps the most complex metallurgical operation that exists, and therefore it will be necessary to enter into some detail on the subject. Ores containing lead, copper, and silver, are divided into two great classes, according as the lead or the copper predominates. In the former case they are treated as lead ores; and, besides the workable lead, matts are obtained containing silver, copper, and lead, which are subjected to repeated fusions with substances containing more lead. Each fusion gives workable lead, which is cupelled, and the last matts are melted by themselves for black copper, which is afterwards submitted to liquation or amalgamation, to separate the silver which it still contains.

The ores which contain only a small quantity of lead are carefully assorted, and divided into at least two classes, the rich and the poor ores. The latter, according to their nature, are submitted to a *crude smelting*, with or without the addition of pyrites either crude or partially roasted, serving in the latter case as a flux, or using other fluxes if necessary, exactly as in the treatment of copper ores. The earthy gangues are thus separated, and poor matts are obtained, which are roasted once or oftener, and are then concentrated by fusion along with additional ores of the same richness. The products of this operation are scoriæ which are passed back into the crude smelting, and *rich matts*. These matts, after several roastings, are fused with plumbiferous substances and ores rich in silver, especially such as contain lead. The products are workable lead, which is cupelled, and matts which are subjected to a new fusion with plumbiferous matters; lastly, cupreous matts are obtained, yielding argentiferous black copper, which is treated in the manner already described. The fusion of the matts along with lead should be performed at a lower temperature than the crude smelting, in order to diminish as much as possible the loss in lead; this is the process followed at Freiberg in Saxony.

Where substances containing lead are rare or difficult to procure, the fusion of the matts with that metal is replaced by a *fusion of concentration*, and the silver is separated from the new matts by *imbibition*. For this purpose the poor lead is melted separately a little before the tapping of the matt, and is stirred with a fire-iron at the instant when the matts flow into the crucible; the lead then decomposes a part of the sulphide of silver, and passes into the matt, while the reduced silver combines with the rest of the lead and produces workable lead. If this workable lead be not sufficiently rich for cupellation, it serves anew for what is called a rich imbibition; this process constitutes the old Hungarian method. The new matt is treated over again in the same manner, and finally cupreous matts are obtained, which are fused by themselves, and yield argentiferous black copper.

Fig. 496 exhibits in plan, and Fig. 497 in vertical section, following the line A B, the Frankenscharn

works, near Clausthal in the Hartz, for the treatment of argentiferous and cupreous galenas; *a, b, c, d,*

Fig. 497.

are deposited and prepared; *c,* the stamping apparatus; *D,* stream of water which impels the machinery.

Eight parts of ore in the rough state, as taken from the mine, yield one part of schlich, fit for smelting; the content of the schlich in lead is sixty to seventy per cent.; the gangue is quartzose and argillaceous. From ten to twelve thousand pounds of schlich are smelted every twenty-four hours. The furnace is attended by relays of three workmen, and a campaign lasts nine or ten weeks. The products are workable lead, which is cupelled, and matts which contain 0.001 of silver and 0.34 to 0.40 of lead. The last matts obtained are roasted several times, and are then smelted, yielding argentiferous black copper, which is submitted to liquation.

COMBINATIONS OF SILVER.—There are three oxides of silver—a suboxide, a protoxide, and a binoxide. Of these the protoxide alone forms permanent and definite saline combinations.

The *Suboxide of Silver*— Ag_2O —was first obtained by FARADAY, by exposing an ammoniacal solution of the protoxide to the action of air. It separates in the form of a black film.

Protoxide of Silver— AgO —is obtained by adding solution of caustic potassa, or lime, or baryta-water, to the solution of nitrate of silver. The precipitate, when washed, is of a brownish-grey color, anhydrous, tasteless, but soluble, according to GRAHAM, to a small extent in pure water, free from saline matter, and has, when in solution, an alkaline reaction. It is completely reduced to the metallic state by the action of a red heat, or even by the prolonged action of the solar light. In the latter case, however, the black powder which results is possibly the suboxide. By digesting it with caustic ammonia it forms an extremely detonating compound, known as *fulminating silver*, and which, according to GAY-LUSSAC and SERULLAS, is probably an azotide of

silver. This compound, which must not be confounded with the *fulminate of silver*—to be described presently—has hitherto received no application, on account of the extreme danger which attends its preparation and management. It sometimes explodes even while still wet, and should, therefore, be prepared only in small quantities, and handled with the greatest possible caution.

Peroxide of Silver— AgO_2 —was obtained by RITTER by electrifying a weak solution of silver. It deposits in acicular crystals at the positive pole, but is readily converted into the protoxide, and is of no use in the arts.

Chloride of Silver—*horn-silver*— AgCl —is procured by adding a solution of chlorine, of hydrochloric acid, or of chloride of sodium, to nitrate of silver, or to any of the soluble salts of silver, with the exception of the hyposulphite. Thus—

It falls in the form of a curdy precipitate of a white color, but which, by exposure to light, becomes purplish-brown, and ultimately black. In sunshine the change is extremely rapid, more especially if any organic matter be present. It is perfectly insoluble in water, so that the minutest portion of hydrochloric acid, or of a chloride in solution, may be detected by adding to the liquid a drop or two of nitrate of silver. It is sparingly dissolved by concentrated hydrochloric acid, and thrown down upon dilution. It is insoluble in nitric acid and in cold sulphuric acid; but, when boiled in sulphuric acid, it is slowly decomposed. When dry chloride of silver is heated to dull redness in a silver crucible, it fuses, and on cooling concretes into a grey semitransparent substance, which is known as *horn silver*, or *luna cornea*. The presence of moisture is necessary to the blackening effect of light upon the chloride, as when dried in the dark and subsequently exposed to light under an inverted glass over sulphuric acid, no discoloration is produced.

Iodide of Silver— AgI —is precipitated upon adding hydriodic acid, or a soluble iodide, to a solution of nitrate of silver. It is of a dingy yellow color, insoluble in water, and decomposed when heated with potassa. Like the chloride, it is discolored by light, and hence its use in DAGUERRE'S photographic process—the plate of silvered copper intended to receive the image in the camera being prepared by exposing it in a box containing iodine. The iodide is distinguished from the chloride, not only by its yellow color, but also by its being insoluble in ammonia, which constitutes its special characteristic.

Bromide of Silver— AgBr —is an insoluble yellowish substance, formed in the same manner as the iodide, and having analogous properties.

Nitrate of Silver— AgO NO_3 —constitutes the most important salt of this metal. It is obtained by dissolving silver in nitric acid diluted with three parts of water; nitric oxide is disengaged, and if the silver contain copper, the solution will have a bluish tinge; if gold, that metal will remain undissolved in the form of a black powder. The solution of nitrate of silver should be perfectly clear and colorless. It is caustic, and tinges

animal substances of a deep yellow, which, by exposure to light, becomes a deep purple or black stain. It is the essential ingredient in many of the washes employed for dyeing the hair, and in the composition of the so-called *indelible* inks for marking linen; but in point of fact, cyanide of potassium will remove the black stain produced by any of the preparations of silver. The crystals are colorless, transparent, anhydrous tables, soluble in an equal weight of cold, and in half their weight of boiling water. Alcohol also dissolves about one-fourth of its weight of this salt at its boiling point, but deposits nearly the whole as it cools. When heated in a silver crucible, the nitrate fuses into a grey mass, and, if cast into small cylinders, forms the *lapis infernalis* or *lunar caustic* of the surgeons. Ivory, marble, and several other bodies may be stained black, or even silvered, by soaking them in a solution of nitrate of silver, and fully exposing them to the action of the sun's rays. A plate of copper, introduced into a solution of this salt, occasions a brilliant precipitation of crystalline silver, and the copper is oxidised and dissolved by the acid. The introduction of mercury into the solution causes a beautiful crystalline deposit of silver, known as the *arbor Dianæ*. To obtain this crystallization in its most perfect state, the solution should contain a little mercury; and the mercury put into it should be already combined with one-sixth its weight of silver.

Several recipes for indelible or marking inks, formed with nitrate of silver, are given in Vol. II., page 381.

Fulminate of Silver— 2 Ag O , $\text{Cy}_2 \text{ O}_2$.—This curious and dangerous compound is prepared as follows:—One hundred grains of fused and finely-powdered nitrate of silver are added to an ounce of warm alcohol, and the mixture stirred in a sufficiently large glass basin. An ounce of fuming nitric acid is then added, and presently a violent effervescence ensues, and a powder falls. As soon as this appears white, cold water is added, and the powder is immediately to be collected upon a filter, washed, and carefully dried at a temperature of 100° . In collecting and handling this powder, the utmost caution is requisite. It should be made in small quantities only, and touched with nothing hard; for it has sometimes exploded upon the contact of a glass rod even under water. The feather of a common quill serves to collect it; and it should be kept in a wide-mouthed vessel covered by paper, and by no means in a stoppered or even a corked phial, as serious accidents have arisen from its unexpected explosion. In short, one cannot be too careful in meddling with it, and its use for fulminating balls and other purposes of amusement is highly dangerous. It detonates in the quantity of a grain, or even half a grain, with great violence, when heated or touched by any hard body. The nature of this substance has been investigated by LIEBIG and GAY-LUSSAC, who have shown that it is a compound of two equivalents of oxide of silver with one of fulminic acid.—*Brande*.

Sulphide of Silver— Ag S —may be obtained by heating finely-divided silver, or plates of silver, with sulphur. It is a grey crystallizable compound, considerably more fusible and much softer than silver. It is the presence generally of sulphide of hydrogen which occasions the

tarnish upon silver, and which, though only superficial, is a great obstacle to many applications that might otherwise be made of this valuable metal.

Sulphate of Silver— Ag O , SO_3 —is deposited when sulphate of soda is mixed with nitrate of silver. It is also formed by boiling silver with its weight of sulphuric acid. It forms a white saline mass, easily fusible. Upon the large scale, small portions of gold may be most economically separated from large quantities of silver, by heating the finely-granulated alloy in sulphuric acid. The gold remains in the form of a black powder, and the sulphate of silver may be decomposed by the action of metallic copper. The silver is precipitated in a pulverulent state, and, with a little borax or other vitrifiable flux, is fused, and cast into ingots. The sulphate of copper is obtained in the crystallized state by evaporating the residuary liquid.

Hyposulphite of Silver— Ag O , $\text{S}_2 \text{ O}_2$ —is formed by digesting carbonate of silver in hyposulphurous acid. It crystallizes in permanent prismatic crystals, soluble in two parts of cold water. Hyposulphite of silver is formed by dropping a weak solution of nitrate of silver into a very dilute solution of hyposulphite of soda. A white cloud is at first produced, which redissolves on agitation. On adding more of the precipitant, the cloud reappears, and aggregates into a grey precipitate, which is the hyposulphite. The solubility of argentine compounds in hyposulphites has led to an important application of the latter in photography, for the purpose of fixing the designs by the removal of all adhering or unchanged salt of silver.

Carbonate of Silver is precipitated in the form of a white insoluble powder, by adding carbonate of potassa to nitrate of silver. It blackens by exposure to light, and is easily decomposed by heat. Carbonate of ammonia only throws down a portion of the nitrate, and forms a triple *ammonio-carbonate* of silver.

The other salts of silver are of too little importance to call for special notice.

ALLOYS OF SILVER.—Silver unites difficultly with *iron*. Upon fusing silver with that metal, the alloy separates into silver retaining about one-thirtieth of iron, and iron retaining about one-eightieth of silver. The latter has a peculiar hard and crystalline texture.

When silver and *steel* are fused together, an alloy is formed which appears perfect while in fusion, but globules of silver exude from it in cooling, which shows the weak affinity of the metals. At a very high temperature the greater part of the silver volatilizes; but a portion, equal to about one in five hundred, remains, constituting a perfect alloy known as *silver-steel*, and which is admirably adapted to the formation of cutting instruments.

Lead and silver form a very brittle dull-colored alloy, from which the lead is easily separated by cupellation. When fused lead, containing silver, is suffered to cool slowly, the lead which first concretes forms granular crystals, and is nearly pure, while almost the whole of the silver is contained in the liquid portion. The separation of the two metals in this way constitutes PATTISON'S process.

With *zinc* silver readily combines, producing a brittle bluish-white granular alloy. When a mixture of eleven

of zinc and one of silver is highly heated in an open crucible, it burns, and the whole of the silver is sublimed with the oxide of zinc.

With *tin* silver forms a white, hard, brittle alloy. *Antimony* also forms a brittle white alloy, the density of which exceeds the mean of its components. The greater part of the antimony volatilizes during protracted fusion; and the whole may be separated in the form of oxide by roasting.

Bismuth and silver may be combined by fusion. The alloy is brittle, yellow-white, and lamellar, exceeding in density the mean of the components. The density of an alloy of equal weights of bismuth and silver is 10·7.

Arsenic, fused with silver, forms an alloy composed of 100 silver and 16 arsenic. It is grey, brittle, granular, and by long fusion great part of the arsenic volatilizes. It may be entirely got rid of by roasting.

With *mercury* silver readily amalgamates. When red-hot silver is thrown into heated mercury, it dissolves; and when eight parts of mercury and one of silver are thus combined, a granular crystalline soft amalgam is obtained, the density of which exceeds the mean. When a solution of this amalgam in liquid mercury is squeezed through chamois leather, the excess of mercury, carrying along with it only a small portion of silver, goes through, and the solid amalgam is left behind.

Standard Silver.—The most important alloy of silver is that which it forms with copper. On account of its softness, silver is seldom employed in the pure state; by the addition of a small proportion of copper, it is rendered harder and more sonorous, while the color of the metal is scarcely impaired. A mixture of seven parts of silver and one of copper still retains a decided white color, although of a less pure tint than that exhibited by virgin silver.

The alloy of silver with copper constitutes plate and coin; the proportions are fixed by the legislature of the country in which the mixture is worked. In this country the same alloy is employed both for the purposes of the mint and the uses of the silversmith; it is composed of 11·1 of silver, and 0·9 of copper, and this mixture is known by the name of *standard silver*. A pound troy, therefore, of the standard silver of this country consists of eleven oz., two dwts. pure silver, and eighteen dwts. of copper. Its density is 10·3; its calculated density, according to the mean of the components, 10·5; so that the metals dilate a little on combining.

To prevent fraud, all silver vessels are required to be stamped by the Goldsmiths' Company, who are empowered by government to search all silversmiths' shops, and seize all articles which have not been impressed with the Hall mark of the company. For the assay of the articles, and the impression of the company's stamp, attesting its quality as standard silver, one shilling and sixpence per ounce on the weight of the object is charged. Of this amount the larger proportion is paid over to the government in the form of a tax, whilst a small sum is retained as a compensation for the trouble incurred in making the assay.

In France three different standards are employed.

The alloy used for the silver currency of the country is composed of nine parts of silver, and one of copper; for plate, a mixture of 9·5 parts of silver to 0·5 of copper is employed, whilst for small articles of silver used for ornaments, an alloy of eight parts of silver to two of copper is allowed.—*Phillips*.

The silver coins of the ancients and many Oriental silver coins are nearly pure; they only contain traces of copper and of gold.

When silver alloyed by copper, such as standard silver, is exposed to a red heat in the air, it becomes black from the formation of a superficial film of oxide of copper. This may be removed by immersion in hot diluted sulphuric acid, and a film of pure silver then remains, of a beautiful whiteness; this is called *blanched*, or *dead silver*. It is usual to employ this process in order to improve the color of objects formed of alloyed silver; the article, when heated nearly to redness, is plunged, while still hot, into water acidulated either with nitric or sulphuric acid; the external oxide of copper is thus entirely removed; and the matted appearance of the pure silver, which now forms the surface, soon gives place to a bright polish by rubbing with a burnisher. The blanks for coin are treated in this way before they are struck; whence the whiteness of new coin, and the darker appearance of the projecting portions occasioned by wear, in consequence of the alloy being uncovered. Articles of plate are often deadened or matted by boiling in bisulphate of potassa, which acts in the same way as the dilute sulphuric or nitric acid.

Silver Solder consists of—

Silver,	667
Copper,	233
Zinc,	100

SILVERING.—Almost all kinds of silvering are now usually performed by electro-chemical deposition, and for full details of the process, the reader is referred to the article *ELECTRO-METALLURGY*, Vol. I., page 800, *et sequitur*. When the term *silvering* is applied to mirrors, it generally means the application of a compound of tin and quicksilver, so that, in that sense, the word is misapplied; but, by Mr. DRAYTON's process, described Vol. II., page 227, a coating of actual silver is deposited upon the plate of glass, and in that case, therefore, the term is strictly applicable.

Silver is hammered out into thin leaves in the same manner as gold; and the account of the process given in the article on that metal, Vol. II., page 288, will therefore suffice for both. When silver-leaf is to be applied to the surfaces of bodies, the methods prescribed for gold-leaf, Vol. II., page 290, are also generally suitable. Among the metals, copper or brass are those on which the silverer most commonly operates, and frequently the white alloy of nickel. Iron is seldom silvered, but the process is essentially the same. The principal steps of the operation are summarily described by Dr. URE as follows:—

1. The *smoothing down* the sharp edges, and polishing the surface of the copper, or other metal, to be silvered.

2. The *annealing*, or making the piece to be silvered

red-hot, and then plunging it in very dilute nitric acid, till it be bright and clean.

3. *Pumicing*, or clearing up the surface with pumice-stone and water.

4. The *warming* to such a degree merely as, when it touches water, it may make a hissing sound; in which state it is dipped in very weak aquafortis, whereby it acquires minute insensible asperities, sufficient to retain the silver leaves that are to be applied.

5. The *hatching*.—When these small asperities are inadequate for giving due solidity to the silvering, the plane surfaces must be hatched all over with a graving tool; but the chased surfaces need not be touched.

7. The *charging*, the workman's term for silvering.—This operation consists in placing the silver leaves on the heated piece, and fixing them to its surface by burnishers of steel, of various forms. The workman begins by applying the leaves double. Should any part darken in the heating, it must be cleared up by the scratch-brush.

The silverer always works two pieces at once, so that he may heat the one, while burnishing the other. After applying two silver leaves, he must heat up the piece to the same degree as at first, and he then fixes on with the burnisher four additional leaves of silver; and he goes on *charging* in the same way four or six leaves at a time, till he has applied, one over another, thirty, forty, fifty, or sixty leaves, according to the desired solidity of the silvering. He then burnishes down with great pressure and address, till he has given the surface a uniform silvery aspect.

Silvering by the precipitated Chloride of Silver.—The white curd obtained by adding a solution of common salt to one of nitrate of silver, is to be well washed and dried. One part of this powder is to be mixed with three parts of good pearlash, one of washed whiting, and one and a half of sea-salt. After clearing the surface of the brass, it is to be rubbed with a bit of soft leather, or cork moistened with water, and dipped in the above powder. After the silvering, it should be thoroughly washed with water, dried, and immediately varnished. Some use a mixture of one part of the silver precipitate with ten of cream of tartar, and this mixture also answers very well. Others give a coating of silver by applying with friction, in the moistened state, a mixture of one part of silver-powder precipitated by copper, two parts of cream of tartar, and as much common salt. The piece must be immediately washed in tepid water, very faintly alkalized; then in slightly warm pure water; and, finally, wiped dry before the fire.

The inferior kinds of coated buttons get their silver coating in the following way:—Two ounces of chloride of silver are mixed up with one ounce of corrosive sublimate, three pounds of common salt, and three pounds of sulphate of zinc with water, into a paste. The buttons being cleaned are smeared over with that mixture, and exposed to a moderate degree of heat, which is eventually raised nearly to redness, so as to expel the mercury from the amalgam, formed by the reaction of the horn-silver and the corrosive sublimate. The horn-silver thus acquires a silvery surface, which is brightened by clearing and burnishing.—*Ure*.

ESTIMATION OF SILVER.—The behavior of various reagents with solutions of silver is given in a tabular form in the article on GOLD, Vol. II., page 269, to which the reader is referred. In general, the *soluble* salts of silver are recognized by furnishing a white precipitate with hydrochloric acid and the soluble chlorides, which blackens by exposure to light, and which is readily soluble in ammonia; and by affording metallic silver upon the immersion of a plate of copper. The salts *insoluble in water* are mostly soluble in ammonia; and when heated on charcoal before the blowpipe, they afford a globule of silver. A yellow precipitate on the addition of phosphate of soda and of the soluble arsenites, a red-brown by arseniates, a crimson by the chromates, and white by ferrocyanide of potassium, are further characteristics of the soluble salts of silver.

Tin and lead are the most rapid precipitants of metallic silver from the nitrate; cadmium, zinc, copper, bismuth, and antimony are more slow in their operation, and mercury still more tardy. Chloride of silver is rapidly reduced by most of the metals which form soluble chlorides, such as zinc, iron, cadmium, cobalt, and arsenic. Zinc, copper, and arsenic rapidly reduce the ammoniacal solution of oxide of silver. Of all the metallic precipitants, zinc and cadmium are the most effective; but when zinc or antimony are used, the separated silver contains those metals.

The solubility of silver in nitric acid, and the complete insolubility of its chloride in acid solutions, render the separation of silver from other metals in most instances an easy operation. When its amount is to be estimated quantitatively, the alloy or pulverized ore is dissolved in nitric acid, and the precipitation of the silver in the form of chloride is effected by the addition of a small excess of hydrochloric acid. In order that a dense precipitate may be obtained, the solution should be heated nearly to the boiling-point previous to the addition of the precipitant. When the whole of the chloride has settled at the bottom of the vessel, the supernatant liquor is carefully drawn off by means of a glass siphon; and the chloride, after being well washed by repeated decantations with water slightly acidulated with nitric acid, is transferred to a thin porcelain capsule, the weight of which has been accurately ascertained and noted down. The chloride, when placed in this capsule, is first carefully dried in a water-bath, and then heated over the flame of a gas-burner or spirit-lamp, until it has become fused, when the crucible and its contents are again weighed. The difference between the first and second weighings gives the amount of the chloride, from which that of the silver can be deduced by the simple proportion:—

As 100 : 75.27 :: K, or the weight of chloride obtained; since every 100 parts of the chloride correspond to 75.27 parts of metallic silver.

ASSAY OF THE ALLOYS AND ORES OF SILVER IN THE DRY WAY.—In this process the object sought is to obtain the silver and other metals that may be present in the form of an alloy with lead, which is afterwards passed to the muffle and cupelled in the ordinary way; in the latter, the method adopted is founded upon the simple process which has just been described.

In assaying the ores of silver, the preliminary operations to which the minerals are subjected, and the form of the cupels and other apparatus employed, have been fully described in connection with the analogous processes followed in the assaying of gold ores; and, therefore, it will be quite unnecessary to repeat them in this place. To obtain an alloy with lead, with a view to cupellation, ores of silver, in which the metals that are present exist in the form of reducible oxides, are commonly fused with a mixture of litharge and finely-powdered charcoal. The proportion of litharge employed for this purpose, says PHILLIPS, must be varied according to circumstances, as the resulting button of alloy should not be too rich, since in that case a portion of the silver is lost in the slag; nor too poor, as the cupellation would then occupy a long time, and a loss through sublimation be entailed. In ordinary cases, if four hundred grains of ore be the quantity operated on, a button of two hundred grains will be a very convenient amount for cupellation; and this may be obtained by the addition of three hundred grains of litharge, and from seven to eight grains of finely-powdered charcoal. The whole is to be well mixed with two hundred grains of carbonate of soda, on a sheet of highly-glazed paper, and afterwards introduced into an earthen crucible, of which it should not fill more than two-thirds the capacity. This is now covered with a thin layer of borax, and fused in an ordinary assay furnace—care being taken to withdraw it from the fire as soon as a liquid and perfectly homogeneous slag has been obtained, as the unreduced litharge would otherwise be liable to cut through the pot and spoil the experiment. When it has sufficiently cooled, the crucible is broken, and the button of alloy obtained is passed to the cupel. When other minerals than oxides or carbonate are to be examined, the addition of charcoal, or any similar reducing agent, becomes in many instances unnecessary, as litharge readily attacks all the sulphides, arsenio-sulphides, *et cetera*, and oxidises nearly the whole of their constituents, with the exception of silver, whilst a proportionate quantity of metallic lead is at the same time set free. The slags formed in this way contain the whole of the excess of litharge added; and the button of alloy produced is subjected to cupellation in the usual manner.—*Phillips*.

In the assay of alloys of silver by cupellation, the directions which are given in Vol. II., page 303, in connection with the assaying of gold, render unnecessary a repetition of all the details of the process, which consists, as there stated, in the oxidation of the lead and other oxidisable metals, and their absorption by the cupel. From the circumstance that the plate and silver money of all European nations are alloyed with copper, the mixtures of these metals are those which most frequently engage the attention of the assayer; and the point to be chiefly attended to is the amount of lead necessary to be added to perform the cupellation efficiently. This amount should be greater, in proportion as the quantity of copper is more considerable; but, in cupelling an alloy of silver and copper, the same amount of lead cannot safely be added as in treating an alloy of copper and gold, as the greater volatility of the silver would cause a consider-

able loss of that metal before the whole of the lead could be absorbed. In this case, therefore, the following table, showing according to D'ARCET, the amount of lead necessary to effect the proper cupellation of various alloys of silver and copper, must be substituted for that given at the page above referred to:—

Standard of silver.	Amount of copper alloyed.	Quantity of lead necessary.	Quantity of lead in relation to that of copper.
1000	0	3-10th*	0 to 0
950	50	3	60 to 1
900	100	7	70 to 1
800	200	10	50 to 1
700	300	12	40 to 1
600	400	14	35 to 1
500	500	16 to 17	32 to 1
400	600	16 to 17	27 to 1
300	700	16 to 17	23 to 1
200	800	16 to 17	20 to 1
100	900	16 to 17	18 to 1
Pure copper 1000	1000	16 to 17	16 to 1

* Even with pure silver it is found necessary to add a little lead on the cupel, as the button would not otherwise assume the rounded form which is required.

In this table the numbers in the third column, which express the quantity of lead necessary to be added in each case, are multiples of the weight of alloy on which the operation is performed. Hence, in the third line, for example, in which the alloy consists of 900 of silver, and 100 of copper, for each grain of alloy taken, seven grains of lead will be necessary; and as each grain of alloy contains only one-tenth of its weight in copper, it follows that the ratio of the lead to the copper is as seventy to one. It will be observed that, even with pure silver, it is found necessary to add a little lead on the cupel, the reason of which is, that the button of silver would not otherwise assume the rounded form required. It will be remarked, also, that here, as in the table given for an alloy of gold and copper, the proportion of lead to be employed for a silver alloy below the standard of 500, remains constantly the same.

Although silver is not appreciably volatilized when melted alone, yet it is so to a certain extent in the presence of lead; and therefore the cupellation should be made at the lowest temperature at which the absorption of the litharge can be effected; and even when every precaution is used, there is always a loss of silver in cupellation, for which allowance must be made in finally calculating the per centage. The table adopted for this purpose at the French mint is given in Vol. II., page 304, to which the reader is referred.

When other metals besides lead and silver are present in an alloy, the cupel usually affords indications, from which it is easy to judge of their nature, and roughly of the amount in which they exist. Mr. PHILLIPS, in his excellent manual of metallurgy, gives the following directions for this purpose:—Pure lead stains the cupel a straw-yellow color, sometimes verging on orange. Copper gives a grey or dark-brown tint, according to its quantity. Iron produces a black stain, which is chiefly formed shortly after the commencement of the operation, and gives rise to a dark ring around the sides of the cupel. Zinc leaves a yellowish stain on the cupel, and produces, during the process of cupellation, a luminous white flame and abundant fumes of the same color, which carry off

with them a considerable amount of silver. Tin produces a grey slag, and antimony leaves a spongy yellow scoria, which causes the circumference of the cupel to effloresce and split off. The two last-named metals render the cupellation of the alloys in which they exist extremely difficult, and necessitate the employment of a large quantity of pure lead, in order to carry off the insoluble oxides formed. When assays of alloys containing silver are frequently to be made by cupellation, it will be found extremely convenient to keep in the laboratory a supply of poor lead, ready weighed out into pieces of fifty and one hundred grains; by this means the standard of the lead being previously known, it becomes easy, by merely counting the number of pieces added, to know exactly what deduction is to be made for the silver in the poor lead at the termination of the cupellation.—*Phillips*.

Humid Method of Assay.—The operation is the same as that described above under estimation of silver, except that instead of collecting and weighing the argentiferous compound, graduated test liquors are employed, and the silver estimated from the volume of such solutions required to precipitate the silver completely. Although the method by cupellation was found to be convenient, where a number of assays were required to be conducted at the same time, and was therefore, until of late years, exclusively adopted at the different mints, yet the results obtained by this method not being perfectly accurate, the French Government in 1829 appointed a commission for inquiring into the subject; and GAY-LUSSAC, who was one of the commissioners, proposed the adoption of the liquid method of assay, which is now generally practised, not only at the Parisian mint, but also at the similar establishments of this and other countries. Not only is greater accuracy obtained, but by successive improvements in the apparatus, the humid process is now conducted with greater facility and despatch.

In this process the standard of the alloy of silver and copper is determined by means of a solution of chloride of sodium, the strength of which has been accurately determined beforehand. Common salt, without any preliminary purification, is employed for this purpose; and the strength of the solution is so regulated, that a decilitre thereof will exactly precipitate one gramme of pure silver. In proceeding to make an assay, one gramme of the alloy to be examined is dissolved in five or six grammes of nitric acid, and to this is added from a graduated burette the standard solution of common salt, until no further precipitate of the chloride of silver takes place. When, in adding the precipitant, the point of saturation seems to be nearly attained, the bottle must be well shaken after the addition of each successive drop of the solution, in order that the liquor may become clear by the precipitation of the chloride of silver formed. When the whole of the silver has thus been thrown down, the exact quantity of the solution of chloride of sodium employed in its precipitation is read off from the graduated scale; and, by the amount used, the per centage of silver present is at once indicated.

When great accuracy is required in making the assay of a silver coin or a piece of plate, the composi-

tion of which is approximatively known beforehand, two distinct solutions of chloride of sodium are employed:—The first, which is termed the *normal solution*, is of such a strength that one decilitre will precipitate exactly one gramme of pure silver; the second, called the *decimal solution*, is only one-tenth of the strength of the first; and, consequently, a litre of it is required to effect the precipitation of one gramme of silver.

To explain the details of the process, let it be supposed that a piece of silver money of the French coinage is to be assayed, and which, in order to be of the legal standard, should contain eight hundred and ninety-seven thousandths of pure silver. Instead of this, suppose the alloy in question to contain only eight hundred and ninety-six thousandths of silver, so that 1.116 gramme of the mixture corresponds to one gramme of pure silver. This quantity is cut off the coin, accurately weighed, and put into a bottle that admits of being perfectly closed by a glass stopple, where it is dissolved in from five to six grammes of pure nitric acid; and as soon as the solution has been completely effected, one decilitre of the normal solution of salt is introduced. If the alloy contain exactly as much silver as was supposed, namely, eight hundred and ninety-six thousandths, the whole of that metal will be precipitated by the quantity of solution added, and the supernatant liquor will contain no traces of chloride of sodium in excess. But if the standard be higher than was supposed, there will still remain a portion of silver in solution; and if it be less, the whole of the silver will have been precipitated, but the liquor will contain an excess of chloride of sodium.

To ascertain which of these effects has been produced, the bottle is carefully closed with its glass stopple and briskly shaken, until the precipitate has subsided, and the solution become clear. A cubic centimetre of the decimal solution, capable of precipitating 0.001 gramme of pure silver, is then introduced. If any silver remain in solution, the liquor becomes cloudy; and after being again shaken, another centimetre of the decimal solution is added. If the liquor still becomes turbid, it is again shaken and allowed to become clear; a third centimetre of the decimal solution is poured in; and so on until no further cloudiness is produced by the addition of the decimal solution. Supposing that five of the cubic centimetres of the decimal solution, successively added, have produced a precipitate, while the addition of the sixth has not affected its transparency; it may be concluded that, after the precipitation of one gramme of pure silver by the decilitre of normal solution, the liquor still contained at least four-thousandths of a gramme of silver. But as a cloudiness was produced by the fifth cubic centimetre of the decimal solution, and none by the sixth, it is evident that the liquor did not contain more than five-thousandths of a gramme of silver; and, therefore, by adding $4\frac{1}{2}$ thousandths, the exact result is certainly attained within one half-thousandth of the truth. The standard of the alloy under examination will therefore be $896 + 4\frac{1}{2} = 900\frac{1}{2}$ thousandths.

When, on the contrary, the first cubic centimetre of the decimal solution produces no precipitate in the solution of silver, which has already received the decilitre

of the normal liquid, it is evident that the standard of the alloy must be inferior to eight hundred ninety-six-thousandths. In this case, its exact composition is ascertained by means of a standard solution of silver in nitric acid, so adjusted that one litre of the liquor shall contain exactly one gramme of pure silver; this is called the *decimal solution of silver*, and is only employed when the alloy under assay proves to be poorer in silver than was imagined at the commencement of the operation. In using it, a cubic centimetre of the solution is dropped from a pipette into the bottle containing the assay; and it occasions a precipitate of salt exactly corresponding to the same volume of the decimal solution of common salt, which was added for the purpose of ascertaining if all the silver was precipitated. The liquor is then cleared by agitation, and another cubic centimetre of the silver solution is added. If this still produces a cloudiness, the bottle is again shaken; and when the whole of the chloride has deposited, a third measure of the solution is introduced; and so on until the silver solution ceases to cause any precipitate. Assuming that the first five cubic centimetres of the silver solution produced a precipitate, and that on the addition of the sixth the liquor remained perfectly clear, it is probable that the fifth cubic centimetre was not entirely decomposed; and it is usual to assume that four and a half cubic centimetres of the silver solution, have been sufficient to decompose the excess of the chloride of sodium left in the liquor after the introduction of the decilitre of the normal solution. In this case, therefore, it is evident that it will be necessary to subtract four and a half thousandths from the presumed title of the alloy, and that its standard will be correctly expressed by $896 - 4\frac{1}{2} = 891\frac{1}{2}$ thousandths.

Such are the details of the process, which is greatly facilitated in the different mints, and generally where numbers of assays of silver and copper alloys have to be made, by the admirable manner in which the apparatus is arranged. The normal solution of common salt is kept in a large vessel, *v*—Fig. 498—made of sheet-copper, carefully tinned on the inside, and supported on a shelf near the ceiling. To prevent evaporation, it is covered by an immovable lid, through which passes a tube, *w*, descending to near the bottom, for the purpose of admitting air to supply the place of the liquid as it is drawn off; and by means of a gauge, *p*, at the side, the quantity of solution contained in the vessel is indicated. From near the bottom of the vessel proceeds a tube, *t*, furnished with a stop-cock, *d*. The pipette, *P*, which contains exactly a decilitre of the liquid, is connected with the tube, *t*, by another tube, *t'*, which contains a thermometer. The metallic connecting piece, by which the tube, *t'*, communicates with the pipette, *P*, is provided with two stopcocks, *rr'*; the stopcock *rr'*, shown also separately in the figure, is so constructed as to allow the air to escape in proportion as the solution enters the pipette. In conducting an assay, the operator closes the extremity of the pipette with the fore-finger of the left hand, and with the right opens the stopcocks, *rr'*. When the pipette is filled with the normal solution of chloride of sodium a little above the mark *m*, the taps, *rr'*, are

closed; and the pipette remains charged with the solution after the finger is removed. On the table below this apparatus is a sliding support, *s*, on which the bottle containing the solution of the alloy in nitric acid is secured by means of a case of copper, *b*, and near it is a small stand containing a sponge, *n*, covered by a piece of fine linen, and arranged at the exact height of the beak of the pipette. The assayer now slides the plate, *p*, in the grooves of the stand, *s*, so that the sponge may come in contact with the end of the pipette; and, by carefully admitting air through the stopcock, *r'*, the liquor is allowed to descend until it exactly reaches the line, *m*, scratched on the glass. The last drop of the solution, which would otherwise remain attached to the beak, is taken off by the sponge; and as the latter becomes saturated, the solution

passes down through the hollow stem on which the sponge is supported into the cylindrical vessel beneath. The operator now draws the slide forward until it is stopped by a peg, which arrests it when the mouth of the bottle, *b*, is immediately under the beak of the pipette; the stopcock, *r'*, is then again opened, and the solution flows into the bottle.

As it generally happens that several assays are being made at the same time, they are put, when weighed out, into as many bottles arranged in a metal frame like a cruet-stand—Fig. 499—each being marked with its own number, and, by the side of each bottle, is a small cup for holding the stopple. After the introduction of the nitric acid, the stand is placed in hot water for the purpose of facilitating the solution. When this is completely effected, the nitrous fumes are removed from the bottles by gently blowing into them through a glass tube; and a decilitre of the normal solution is added to each in the manner which has just been described.

The bottles are then placed in another metal frame *M*—Fig. 500—which is similarly provided with cases or compartments for each, and is suspended from the extremity of a steel spring, *s*, while it is steadied below by an elastic band, *p*, of vulcanized india-rubber.

Fig. 498.

Fig. 499.

The bottles, after being carefully closed by their stopples, and secured in their places by a kind of collar—Fig. 501—which, when thrown up, is supported by a rest *r*, are well shaken by an assistant, who

Fig. 500.

takes hold of the handles, *o o*, and briskly agitates the whole apparatus for some minutes. As soon as the liquors have in this way been rendered clear, the bottles are removed from the frame *M*, to a black table, divided into compartments, which are numbered to correspond with the numbers on the bottles. The decimal solution, which is contained in a phial with a pipette passing through its stopple, is now employed for determining the exact standard of the several assays. On the surface of the pipette a line is drawn, so graduated as to enable the operator to measure out exactly one cubic centimetre

of the solution, which he does by applying the forefinger to the upper extremity of the tube; and the latter, while thus closed, being removed from the bottle, is then allowed to drop, by the cautious admission of air, until the liquid has fallen to the level of the line marked on the glass. The top of the tube is again stopped by the finger; and the cubic centimetre of solution is transferred to the first bottle of the series, into which it is allowed to flow by simply removing

Fig. 501.

the finger. In the same manner an equal quantity of solution is added to each of the other assays.

The operator now examines each of the bottles in succession, and makes a mark with a piece of chalk on the black table before those bottles in which he observes that a precipitate has taken place. These are again taken to the agitating apparatus, in which they are briskly shaken until the liquors have again become clear, when they are restored to their places on the black table; and another cubic centimetre of the decimal solution is added to each bottle in which a precipitate was obtained by the last operation. This process is continued until all the bottles cease to give precipitates; and, on counting the number of chalk marks before each, the number of cubic centimetres of the decimal solution which have been added to each is ascertained. From this number must be deducted half a centimetre in each case, to allow for the superfluous quantity which may have been added the last time, a portion only of which has probably been decomposed.

The normal solution of chloride of sodium is prepared at the temperature of 59° Fahrenheit; but as the density of the solution varies with the temperature

of the air, it is necessary to construct a table of corrections to be employed when the assays are conducted at a higher or lower temperature. For this purpose the thermometer contained in the tube, *t'*—Fig. 498—should be consulted, and the correction read off from the prepared tables; but, in most instances, the assayer makes an experiment every morning on the saline solution with one gramme of pure silver, and from the result obtained he is enabled to correct any error arising from change of temperature, as well as from want of due care in the preparation of the normal solution.

The standard solution of chloride of sodium is usually prepared in considerable quantities at a time; it is made by dissolving five hundred grammes of common salt in four litres of water, and filtering. The additional quantity of water that would be required for the normal solution, supposing the chloride to be pure, is now added; and the solution is carefully adjusted to the exact standard by adding a decilitre to a solution of one gramme of pure silver in nitric acid. The liquor is clarified by agitation; and by the addition of successive centimetres of the decimal solution either of silver or chloride of sodium, the exact amount of free silver or chloride, as the case may be, remaining after the addition of the decilitre of normal solution, is accurately ascertained.

The decimal chloride solution is prepared by pouring a cubic decilitre of the normal solution into a bottle of the exact capacity of a litre, and filling it up with pure distilled water.

The decimal solution of silver is prepared by dissolving one gramme of pure silver in nitric acid, to which distilled water is added to make up an exact litre of the liquid.

When the alloy under assay contains either mercury or lead, the results obtained by the humid process are not exact, since these metals are precipitated with the silver, and decompose a portion of the normal solution, which vitiates the conditions of the experiment. The presence of mercury is indicated when a difficulty is experienced in obtaining a transparent solution by agitation; and when that is the case, the assay is not to be relied on. The assay of alloys containing mercury may, however, be made by the humid process, by adding a solution of acetate of soda to the nitric acid liquor containing the silver, previously to the introduction of the normal solution, as the acetate prevents the formation of the chloride of mercury.

The silver assays for the Royal Mint are now conducted by the humid method, and the following is a brief outline of the process as communicated by Dr. W. A. MILLER to Mr. TOMLINSON:—Ten grains of the alloy to be assayed are accurately weighed, and dissolved in one hundred and twenty grains of pure nitric acid. The standard solution of salt is so regulated that a thousand grains thereof will exactly precipitate one grain of pure silver. Now, taking the standard of English silver at nine hundred and twenty-five silver, and seventy-five copper, care is taken to keep an excess of silver in the solution; for if salt be in excess, however small, no amount of shaking will get it clear. Accordingly, the pipette *P*, Fig. 498, is charged with the standard solu-

tion to the mark, *m*, which is equivalent to nine hundred and twenty-three grains, a quantity which is capable of precipitating nine hundred and twenty-three grains of pure silver; the liquor is agitated for about a minute, and then allowed to settle. Ten grains of the decimal solution, capable of precipitating one-hundredth of a grain of silver, are now added: if a cloud be produced, a chalk mark is made against the bottle. The liquor is agitated for a minute, a second dose of the decimal solution is added, and if no precipitate is produced, it is thus shown that of the ten grains of the alloy, 9·235 grains consist of pure silver, the rest being alloy; thus showing a result a little below the standard. The standard solution of silver is formed by dissolving ten grains of pure silver in pure nitric acid and diluting it,

so that one thousand grains thereof shall contain one grain of silver.—*Tomlinson*.

STATISTICS.—In statistical returns of the precious metals, gold and silver are usually associated together, and accordingly the reader is referred to the tables appended to the article on GOLD, Vol. II., pages 308 and 309, for tables which exhibit the aggregate and relative amounts of gold and silver obtained from the different countries of the world, the annual consumption of the precious metals, and the amount of gold, silver, and copper monies coined at the mints of Great Britain, France, and the United States. To the ample information afforded by these tables with reference to the present or recent supplies of the precious metals, it will be sufficient to add the following:—

TABLE OF THE QUANTITIES OF SILVER BROUGHT INTO THE MARKET EVERY YEAR, ON AN AVERAGE, FROM 1790 TO 1802.

Old Continent.	Pounds avoirdupois.	New Continent.	Pounds avoirdupois.
ASIA.			
Siberia,	38,500	Central America,	1,320,000
EUROPE.		South America,	605,000
Hungary,	44,000		
Austrian States,	11,000		
Hartz and Hessa,	11,000		
Saxony,	22,000		
Norway,	22,000		
Sweden,	11,000		
France,			
Spain,			
Total of the Old Continent,	159,500	Total of the New Continent,	1,925,000

Thus, towards the close of the last century, the New Continent furnished twelve times more silver than the Old.

The following is HUMBOLDT's estimate of the annual produce of the mines of the New World at the beginning of the present century:—

ANNUAL PRODUCE OF THE MINES OF AMERICA AT THE COMMENCEMENT OF THE NINETEENTH CENTURY.

Political divisions.	Gold.		Silver.		Value of the gold and silver in dollars.
	Mares of Castile.	Kilogs.	Mares of Castile.	Kilogs.	
Vice-royalty of New Spain,	7,000	1,609	2,338,220	537,512	23,000,000
Vice-royalty of Peru,	3,400	782	611,090	140,478	6,240,000
Captain-generalship of Chili,	12,212	2,807	29,700	6,827	2,060,000
Vice-royalty of Buenos Ayres,	2,200	506	481,830	110,764	4,850,000
Vice-royalty of New Granada,	20,505	4,714	2,990,000
Brazil,	29,900	6,573	4,360,000
Total,	75,217	17,291	3,460,840	795,581	43,500,000

Taking the dollar at four shillings, this would give eight millions seven hundred thousand pounds sterling as the total annual produce of the American mines *in gold and silver*. HUMBOLDT further estimated the annual produce of the European mines of Hungary, Saxony, *et cetera*, and those of Northern Asia at the same period, at about one million pounds more.

The production of gold, says McCULLOCH, has very largely increased since 1848, as compared with that of silver; and if this state of things go on, the value of silver, measured in gold, can hardly fail gradually to rise. But it is by no means clear that it will go on.

The supplies of silver are increasing in most parts of the world, particularly in Mexico and Europe. It is to be observed, however, that a comparatively inconsiderable rise in the value of silver, as compared with gold, is sufficient, unless prevented by legislative enactments, to make the latter be used in preference to the former in the currency of those countries in which both metals are legal tender.

In concluding this article, the Editor again begs to acknowledge his obligation to Mr. GEORGE BLAIR of Glasgow, for much valuable matter, and for his kind assistance, at all times cheerfully rendered.

SOAP.—*Savon*, French; *Seife*, German; *Sapo*, Latin.—The article now to be considered is one of the utmost importance, as, with the progress of civilization, it becomes an indispensable necessity to every human being; and as the art of its production is entirely of a chemical nature, the more it is studied under the guidance of chemical principles, the higher in quality and the better suited to its purpose will be the material. The theory which accounts for the union of certain principles of oils with the alkalies in the formation of soaps, is indeed as abstruse as that which relates to some of the most refined instances of affinities. The manufacture of soap is, therefore, strictly scientific; and it behoves those who desire to advance in the art, to study thoroughly the principles involved in it, so that each result may be an advancing lesson for their own profit, while it enables them to repay the benefit they have derived from chemistry, by furnishing, from their experience, new facts for the guidance of others.

Whether the extended use of soap be preceded or succeeded by an improvement in any community—whether it be the precursor or the result of a higher degree of refinement amongst the nations of the earth—the remark of LIEBIG must be acknowledged to be true, that the quantity of soap consumed by a nation would be no inaccurate measure whereby to estimate its wealth and civilization.

Of two countries with an equal amount of population, the wealthiest and most highly civilized will consume the greatest weight of soap. This consumption does not subserve sensual gratification, nor depend upon fashion, but upon the feeling of the beauty, comfort, and welfare attendant upon cleanliness; and a regard to this feeling is coincident with wealth and civilization.

The rich, in the middle ages, concealed a want of cleanliness in their clothes and persons under a profusion of costly scents and essences, while they were equally luxurious in eating and drinking, in apparel and horses. With civilized nations at the present time, a want of cleanliness is equivalent to insupportable misery and misfortune. The remission of the soap duty in Great Britain, which, so long as it remained unrepealed, prevented the adoption of all improvements in the manufacture, has enabled British to compete more successfully with foreign manufacturers; and it may now be hoped that this branch of industry will still further progress, so that an abundant supply of this necessary, and indeed indispensable article of domestic use, may be more easily obtainable by all.

In proof of the injurious influence of the excise duties on this and other branches of manufacture, it may be stated that the process for its production has undergone little or no alteration for the last two or three centuries. Now, however, that the manufacturer is not restricted as to the choice of materials, it remains only for the chemist to supply other and cheaper ones, and to guide the practical man as to the best method of combination; and, doubtless, diligent inquiry will reward those who enter upon the subject in a truly scientific spirit.

The term soap was formerly applied to all compounds consisting of an alkali, an alkaline earth, or a metallic oxide, united to a fatty or oily acid, or other substance of an unctuous or oleaginous nature. This extended meaning of the term is, however, not now recognized; it is now applied to those combinations of grease or oil with the alkalies which, by their peculiar properties and solubility in water, aid the removal of grease and dirt in the processes of washing and scouring. This cleansing influence is due to what is termed a detergency; that is, a power of rendering soluble in water the adhering dirt of the clothes and the skin, to which purpose soap is almost exclusively applied. The alkalies themselves—potassa and soda—possess this property of detergency; and the former, potassa, under the form of wood ashes, was used in the most ancient times by the Hebrews, Egyptians, and Greeks, as an aid to cleansing processes. Free alkali itself, however, possesses a solutive property over fibrous materials, over even human skin, and hence the necessity of combining it in such a manner as to modify this injuriously corrosive action.

The remedy is the substitution of soap, which, by its slight excess of alkali, rendering soluble in and miscible with water all the dirty grease of the clothes and oily exudations from the pores of the skin, is at the same time deterrent itself; for, though composed of oil and alkali in a state of combination, it still possesses the influence of the latter without any of its hurtfulness. Oleate of oxide of lead, formerly called *lead soap*, is insoluble, and constitutes the diachylon plaster of pharmacy. The analogous salts of zinc and lime, formerly termed *zinc soap* and *lime soap*, are also insoluble.

HISTORICAL NOTICE.—Although the word *soap*, or rather *sope*, is occasionally met with in the translation of the sacred records, it must not be supposed that the substance now known by that name was used by the Israelites. The word so rendered, doubtless, refers to the juice of some plant, or more probably to the ashes of a plant; as the substance in question appears to have deterrent properties. The earliest mention of the term *soap*, as applied to the substance now under discussion, occurs in the writings of PLINY, who also describes a process for its preparation differing but little from that pursued at the present day. This writer ascribes its invention to the Greeks, from whom the Romans, and subsequently other nations, derived a knowledge of its manufacture. HOMER makes no mention of soap, and it was doubtless unknown to him. In the excavations at Pompeii a complete soap-boiling establishment was discovered, containing soap still perfect, though it must have been prepared upwards of seventeen hundred years. The Editor was greatly interested inspecting the factory.

The Germans were at a very early period distinguished for their production of superior soap, and hence probably the Latin term *sapo*, from the original German *seipe*, now written *seife*, and from this by a transposition of letters, the English *soap* is derived. Owing, in a great measure, to natural advantages of the country, France is now the great mart for soap, and especially for toilet soaps.

MATERIALS.—The materials used in the manufacture of soap, are the various kinds of oil or fat, resin, and the alkalis, potassa and soda. All oils and fats of whatever kind, vegetal or animal, yield soaps, when treated with alkali, as will be subsequently described. Only a very limited number, however, is used in this manufacture; and these such as may be obtained at a very low price compared with that of the others. In Great Britain palm-oil is probably consumed in greater quantity than any other, and principally in the production of hard soap; for soft soaps, the various kinds of fish-oils, the drying oils from seeds, and tallow are mostly employed.

In France, and on the Continent, olive oil is extensively used in soap-making; and for soft soaps, hemp-seed oil is highly valued.

Tallow, saponified with soda, yields white curd soap; this, formerly much used for domestic purposes, is superseded in great part by the softer, and otherwise superior palm-oil soap. Cocoa-nut oil soap, on account of its property of dissolving pretty readily in salt water, is useful for washing during long sea voyages. Of all soaps, the most emollient are those of palm-oil, castor oil, and of spermaceti; yet these are not nearly so extensively used by the perfumer, or for toilet purposes, as the curd or ordinary tallow soap. Though it is of the utmost importance that the manufacturer should be fully acquainted with the peculiar properties, not only of the oils generally, but of the several individual kinds, still it will not be necessary to repeat here what has already been stated in the article specially devoted to the consideration of that subject.—Vol. II., page 597, *et seq.*

Most of the oils and fats are met with in commerce in a sufficient state of purity for their conversion into soaps without previous preparation.

Palm-oil, however, and occasionally tallow, are exceptions to this rule, and, therefore, the methods most effectual for their purification before being used in the manufacture will be afterwards stated. The destruction of the coloring matter is the object of these processes, and though described with a special view to the decoloration of palm-oil, they are generally equally applicable for tallow and other oils or fats which it may be necessary to purify more completely. The admirable investigations of CHEVREUL relative to the constitution of fatty bodies, and of LIEBIG as to the peculiar behavior of soap with various saline solutions, have greatly simplified the description of the several operations in the soap manufacture; and one can now understand the reason for the several operations, and trace with accuracy the changes that take place throughout.

Nevertheless, much room remains for future investigators in this wide field; and many improvements may still be expected from further research. Tallow, olive, palm, and cocoa-nut oils, oleic acid, and resin are used for the production of hard soaps; fish and seed oils, on the contrary, for soft soaps. The mixture of oleic acid with small quantities of stearic and margaric acids, which is obtained in the separation of stearic acid by pressure, as described under the article CANDLE, affords an excellent soap, the production of which is a secondary

process in stearic-acid manufactories: it is prepared so much the more readily as the fat is already decomposed, and the acid merely requires neutralization with alkali.

Experiments were made by DARCET, LELIÈVRE, and PELLETIER, on the relative value of different kinds of oil and fat in the manufacture of soap. The oils or fats were saponified by means of caustic soda lies, and the products were, therefore, soda soaps. The results of these experiments were as follows:—

Three pounds of olive oil gave a block of soap weighing six pounds ten ounces, which, on exposure to the air for two months, became four pounds fifteen ounces. It was then dry and perfectly solid, of excellent color, resembling that of Marseilles soap. By further exposure in a dry place it became still lighter, owing to loss of water.

Sweet almond-oil soap was found to be next to the olive-oil soap in consistency. This was very white, uniform, and of an agreeable odor. Its weight from three pounds of oil was five and a half pounds; and, after two months' exposure, it lost one pound of water. *Rape-seed oil soap* is of a greyish-yellow hue, is more consistent than that of colza oil, and possesses the peculiar odor of the oil from which it is produced.

Oil of beech-nut soap is of a dirty-grey color, softer than the preceding, and has the smell of the oil. This soap is greasy, pasty, and clammy, and when exposed to the air becomes yellow.

By associating these oils with proportionate quantities of suet or tallow, mixtures will be formed, of which soaps of proper quality and consistence can be made. The soaps made from *poppy oil* are of a dirty grey, without any disagreeable smell; are clammy, and of medium consistence. They become yellow in the air, and, when exposed to cold, become soft at the surface. This oil, when mixed with the greases, yields a soap much resembling in appearance that of olive oil.

Hemp-seed oil soap is of a green color, very pasty, and so soft that the least addition of water renders it liquid. Exposed to the air, it loses its green tint exteriorly, bleaches, and afterwards becomes brown. *Nut-oil soap* is of a yellowish-white color, with but little consistence, is greasy and clammy, and assumes a brown appearance on exposure. *Linseed oil* yields a whitish soap, which, however, becomes yellow by contact with the air. This soap is greasy, pasty, and viscous, of a slight consistence, and powerful odor, and is reduced to a thin paste by a slight addition of water. *Sperm-oil soap* is of a dirty-grey color. It retains the peculiar smell of the oil, becomes reddish-brown and of some firmness, but much less than olive-oil soap.

Soap prepared from *fish oil* is very similar to the last named. *Cod-liver oil soap* differs only in having a more unpleasant smell and less consistency. *Suet or tallow soap* is white and solid, and has a slight odor of the fat. Exposed to the air, it loses water, and becomes brittle. Soap prepared from *lard* is very white, solid, inodorous, and especially valuable for the production of toilet soaps. *Rancid butter* yields a soap which is white, and in properties similar to tallow soap, but retains a rancid smell. *Castor oil* and *spermaceti* soaps are emollient, and especially applicable to toilet pur-

poses. Soap, made from palm oil is little inferior to castor oil or spermaceti soap. Lastly, soaps prepared from drying oils are usually soft and flabby.

The appended table shows the quantity of soap obtained from three pounds of each of the oils mentioned above, saponified with caustic soda solution.

Oil or fat.	Color of the soaps.	Quantity obtained as taken from the frame.	Loss of weight in pounds and ounces.	Time.
Olive oil,	White,	6 lbs. 10 oz.	5 lbs. 0 oz.	2 months.
Sweet almond oil,	White,	5 " 11 "	4 " 6 "	2 months.
Colza oil,	Lemon-yellow,	5 " 14 "	5 " 0 "	15 days.
Rapeseed oil,	White,	6 " 8 "	5 " 0 "	20 days.
Beech-nut oil,	Dirty-grey,	5 " 4 "	4 " 13 "	2 months.
Poppy oil,	Grey,	4 " 8 "	4 " 6 "	45 days.
Hempseed oil,	Green,	5 " 0 "	4 " 14 "	15 days.
Nut oil,	Deep yellow,	4 " 7 "	4 " 6 "	15 days.
Linseed oil,	Yellowish,	5 " 0 "	4 " 12 "	1 month.
Sperm oil,	Dirty-grey,	4 " 12 "	4 " 10 "	15 days.
Fish oil,	Reddish-brown,	4 " 11 "	4 " 8 "	1 month.
Cod-liver oil,	Dirty-grey,	4 " 14 "	4 " 12 "	15 days.
Suet or tallow,	White,	8 " 4 "	6 " 0 "	2 months.
Lard,	White,	8 " 3 "	5 " 0 "	2 months.
Washed rancid butter,	White,	11 " 0 "	7 " 0 "	2 months.

PALM OIL.—The sources, preparation, properties, and composition of this valuable oil, have been fully discussed in a previous article, Vol. II., page 618. It remains here to notice more particularly the treatment to which it is necessary to submit it, to remove the coloring matters, *et cetera*, previous to its employment in the manufacture of soap. Its rapid rise in commercial importance during the last half century exceeds that of nearly every other article imported, as will be seen by the following statistics:—

	Hundredweights.
Imported in 1820,	17,456
" 1830,	213,476
" 1840,	315,503
" 1850,	447,796

At the present time palm oil is imported to the amount of upwards of twenty-five thousand tons annually.

As it arrives in this country, this oil is tinged of a peculiar and characteristic orange-red color, which renders it unfit for use in this manufacture in its natural state. The coloring matter, it should be observed, is not proper to the pure oil, which, in a state of chemical purity, is perfectly colorless. There is associated with the oil, however, and extracted with it from the palm a peculiar principle, which in the course of time undergoes spontaneous decomposition, assuming at the same time a characteristic color.

Numerous processes have from time to time been adopted to effect the decoloration of palm oil, nearly all of which depend upon the application of nascent oxygen produced through the decomposition of various compounds, from which it may be liberated with a greater or less degree of facility.

The old method consisted in the employment of nitric acid; but this method, though not objectionable on account of its cost, has the disadvantage of impairing the peculiar violet odor of the oil upon which its value chiefly depends; whilst, at the same time, though the coloring matter is destroyed, the oil is not perfectly bleached, and hence it yields a soap of a greyish-yellow hue. Neither is chlorine well adapted for the purpose, though the coloring matter is readily decomposed by it; for this agent exerts an injurious action on the oil itself, developing a brown tint, and impairing its

consistence. Nevertheless, chlorine has been used to a great extent for depriving palm oil of its color; the materials for generating the chlorine, namely, binoxide of manganese and hydrochloric acid, or, instead of the latter, chloride of sodium and sulphuric acid, being introduced directly into the melted oil. The changes that ensue when hydrochloric acid is employed, may be shown as follows:—

and when, in the place of hydrochloric acid, chloride of sodium and sulphuric acid are used, the reaction may be thus stated:—

As to the precise manner in which chlorine effects the destruction of coloring principles, this is a question upon which there is much difference of opinion. It cannot be questioned, however, that the injurious action of free chlorine on the substance of oils is owing to its powerful affinity for hydrogen, and that by the abstraction of this element more or less completely from the oil, entirely new and probably substitution compounds are produced, which will account for the alteration in the color and consistence of the oil.

Of all methods of bleaching palm oil, that which effects the decomposition of the coloring matter most completely, is that originally proposed and patented by Mr. WATT, in which the decoloring agent is nascent oxygen produced by the decomposition of chromic acid. The process is commenced by heating the oil by steam in an ordinary boiling cauldron for half an hour; it is then allowed to stand at rest to deposit impurities, and when cooled down to about 130°, it is drawn off from the sediment and condensed steam, and placed in wooden vessels, each capable of containing two or three tons. To each half tun of oil, thus far freed from extraneous matters, the following mixture is added; a saturated aqueous

solution of twelve and a half pounds of bichromate of potassa, four pounds of concentrated sulphuric acid, and about twenty-five pounds of strong hydrochloric acid. These are the proportions recommended by the patentee, but are not always strictly adhered to; many bleachers using to the above quantity of oil, ten pounds of the bichromate, and forty of the hydrochloric acid. After being well agitated with the mixture for a few minutes, the oil becomes of a black color; in a short time, however, this changes to dark green, and soon afterwards to light green; and at the same time a thick froth appears on the surface indicating the termination of the reaction. The oil is now examined by taking out a small portion and allowing it to settle, and if not sufficiently decolorized an additional portion of the bleaching mixture is added.

After complete decoloration, which is effected in from ten to fifteen minutes, the oil is permitted to remain undisturbed for about half an hour, so as to allow the deposition of the aqueous solution of chloride of chromium, sulphate of potassa, and other foreign matters; after which the clear oil is drawn off into a wooden vat, mixed with a little fresh water, and again heated for a short time by means of steam.

After being once more allowed to rest to deposit water, *et cetera*, the oil may be siphoned or otherwise drawn off, and is fit for use.

As already mentioned, the decoloration is effected in this process by the agency of nascent oxygen. When the solution of bichromate of potassa and hydrochloric acid are mixed, the acid of the bichromate is liberated, the oxygen of the potassa seizes the hydrogen of the acid forming water, and the chlorine unites with potassium to produce chloride of potassium as represented in the annexed equation:—

After this decomposition, the mixture, containing an excess of hydrochloric acid, is added to the melted oil, and on coming in contact with the organic matter, a further change takes place between the hydrochloric and chromic acids. The latter is reduced to sesquioxide of chromium, and this with hydrochloric acid yields sesquichloride of chromium; water is formed, and oxygen is set free as follows:—

The liberated oxygen is seized by the coloring matter, and the green sesquichloride of chromium, chloride of potassium, *et cetera*, are found in solution in water at the bottom of the vat. The sulphuric acid directed to be added by the patentee, does not appear to be essential to the operation, and is indeed omitted by many bleachers. Oil once bleached by this process may be preserved from acquiring odor, and the soap made from it does not become tinged like that made from oil bleached by other methods.

Another process for bleaching palm oil, depending, like the preceding, on the decoloring power of oxygen at the instant of its liberation, was patented some years ago by Mr. WATSON. In this method manganate of potassa or chameleon mineral is used as the source of oxygen, and after solution in water is added to the melted oil in the proportion of one-twentieth of its weight, the oil being placed in a wooden cask, and mixed with dilute acid. The whole is to be well mixed, and gradually heated to 212°, and maintained at that temperature for an hour. The rest of the process is conducted precisely as directed when bichromate of potassa and hydrochloric acid are employed.

On account of the tendency of the solution of manganate to spontaneous decomposition, the mixture of dilute acid and fat, to which it is to be added, should be at the lowest temperature consistent with its fluidity. Owing to this peculiarity of the manganate, as well as for many other reasons, it is not likely to supersede the employment of bichromate.

When palm oil is to be used in the production of yellow soap, the most economical mode of bleaching is by the process patented by Mr. ARTHUR DUNN. This method, which is also applicable to other oils and fatty matters of a like nature, consists in the exposure of the oil to the combined influence of air and heat. The air is forced beneath the surface of the oil through pipes, by means of a blowing apparatus, and then allowed to rise through the liquid in numerous small streams; the oil being maintained at a temperature between 170° and 230° by steam pipes or other means. A hood communicating with a chimney is placed over the vessel containing the oil, for the purpose of conducting away the unpleasant vapors which are disengaged. This process appears to be an improvement of the method first recommended by Mr. CAMERON through the Society of Arts. This gentleman directed the heated oil to be violently agitated by means of a horizontal fan, revolving at the rate of about six revolutions a minute, and it was stated that by this method four tons of oil may be decolorized in ten hours at one operation, and at the expense of half a ton of coals.

All that is essentially necessary to effect the bleaching is obviously the exposure of the oil to the combined influence of air and heat, and with this view the process of Mr. DUNN seems as complete a method as could be devised. According to PARNELL, the oil should not be maintained at a temperature exceeding 180° during the operation of blowing in the air. He recommends, however, that at the commencement of the process it be heated to 212°, and then suffered to cool a little. This is necessary, inasmuch as the air has but little effect as long as water is present; but when this is completely expelled, the bleaching commences immediately. The oxidising action of the air on the coloring matter of palm oil, as PARNELL observes, seems to be accelerated by combining the influence of light with that of heat. With this end in view, the oil is sometimes placed in a thin layer, on the surface of a large shallow uncovered vat. Several of these vats, each about a foot in depth, may be heated by means of steam passed through serpentine

lead pipes proceeding from a common boiler; one extremity of each tube may terminate in a receiver for the condensed water, and the latter may be returned to the boiler. Each vat is first two-thirds filled with water, and when this is become hot, a sufficient quantity of palm oil is introduced to form when fluid a layer of about two inches in depth, and this should be maintained during the whole process at a temperature as near 212° as possible. To preserve an equal temperature throughout the fluid, the steam may be admitted at opposite ends of the vat, and separated in contrary directions by two distinct serpentine tubes. Both air and light having access, the time required for the decoloration of the oil at a temperature approaching to 212°, is from ten to fifteen hours: the thinner the stratum of oil, the more rapid is the process. The rapidity of the bleaching action is not sensibly lessened by loosely covering the containing vessel, provided the removal of the air over the surface of the oil is not much interfered with; but if exposed to a temperature of 212° in a closed vessel, so that although light and heat have access, the air is excluded, the oil does not then become bleached; hence PAYEN, who made these observations, suggests the propriety of adopting such an expedient as will, while not excluding air, partially prevent the great loss of heat which occurs from the extensive surface of oil presented to the air in the open vessels commonly used in this method of decoloration. The bleached oil, which while fluid retains a fawn-colored tint, is after solidification of a greyish-white color.

RESIN.—Besides oil and alkali common resin or colophony also forms an important ingredient in the production of soap. The sources and method of procuring this substance have been fully discussed in a separate article, and it only remains here to treat of it as a constituent of soap. The kind used is that yielded by the common turpentine, produced by and extracted from the several species of pine.

Though employed in the fabrication of soap as a partial substitute for oleaginous or fatty material, resin does not possess a similar constitution to these matters, and, therefore, does not suffer an analogous alteration in the process of saponification. Resin contains no oxide of glyceryle or any similar body, nor indeed any base whatever. UNVERDORBEN, who made a careful examination of it, found it to be an indefinite mixture of two distinct substances possessing very decided acid properties, and which he termed sylvic and pinic acids, the latter of which is readily soluble in cold alcohol of specific gravity 0.86, and the former nearly insoluble in this liquid. The introduction of too large a proportion of resin into soaps, gives to the latter a very dark color, and also renders them much too soft for application to the purposes for which hard soaps are used. Resin is used only in the production of yellow soap.

ALKALIES.—The alkaline ingredients employed in the soap manufacture are, as already noticed, potassa and soda. Both these articles are met with abundantly in commerce in the state of carbonate, and in this condition purchased by the soap manufacturers.

The crude carbonate of potassa, termed *potash* or

pearlash, is prepared by calcining in an iron pot the residue of the evaporation of a lie obtained by digesting wood ashes in water. Its production has been fully described under the article POTASSIUM. Besides carbonate of potassa, it contains in considerable proportions, chloride of potassium, sulphate of potassa, and other salts. These, however, do not interfere materially with its application to the soap manufacture.

The carbonate of soda of commerce is variously designated, according to the source whence it is obtained. Barilla, a very impure variety, is in appearance a grey or bluish-grey mass, and is imported from Spain and the Levant. It is procured from the plants of the order *Chenopodiaceæ*, which, being cultivated on the coast, are, when ripe, cut down, dried, and burned in heaps; the resulting ash is barilla. Besides carbonate of soda, it contains sulphate of soda, sulphide and chloride of sodium, carbonate of lime, alumina, silica, oxide of iron, and carbonaceous matters which have escaped combustion. The quantity brought to this country is now very small; indeed soap manufacturers generally have abandoned its use. *Kelp*, another very impure carbonate of soda, is prepared in a similar manner to barilla, from the plants of the order *Algaceæ*. It contains the impurities which exist in barilla, and, in addition, an alkaline iodide. Kelp is used to a far greater extent by soap manufacturers than barilla, but its value as a source of soda is very insignificant. The greatest source of soda, both as applied to the production of soap and to all other purposes, is the *white ash* or soda ash of commerce, procured by the decomposition of common salt. The introduction of this material, though it was effected with much difficulty, has been the greatest stimulus the soap manufacture has ever received. Mr. JAMES MUSPRATT of Liverpool, who was the first to carry out LEBLANC's process on a large scale, in the year 1824, was compelled to give away soda by tons to the soap-boilers before he succeeded in convincing them of the extraordinary advantages to be derived from it. As soon, however, as he effected this, and when the soap-boilers discovered how much time and money they saved by using artificial soda, orders came in so rapidly that the Editor's father, to satisfy the demand, had his crude soda discharged red hot into iron carts, and thus conveyed to the soap manufactories.

From that period a constant race was kept up between soap-making and the artificial production of soda. Every improvement in LEBLANC's system was followed by an extension of the soap trade; and it is a curious fact, that the seaport of Liverpool exports annually more soap at present, than did all the ports of Great Britain previous to the conversion by Mr. MUSPRATT, on the large scale, of chloride of sodium into crude carbonate of soda. The manufacture of soap has, on the other hand, been a powerful stimulus to the preparation of soda, and of the important secondary product—chloroxide of calcium, or *bleaching powder*—two substances which are so intimately allied with almost all branches of chemical manufactures. Thus soap occupies one of the most important pages in the history of applied chemistry. The increase in the consumption of this article has led, moreover, to the dis-

covery of new materials for its production, and has opened new channels to commerce.

When the soda prepared from common salt was first introduced into the soap manufacture, for making yellow soap, the fabricators purchased it in the form of *black ash* or *ball soda*. This, at that time designated also British barilla, is the residue of the calcination, in a reverberatory furnace, of a mixture of sulphate of soda, chalk or broken limestone, and small coal; and when lixiviated with cold or luke-warm water, affords a solution of carbonate of soda, containing also a small quantity of caustic soda and sulphide of sodium, together with a portion of undecomposed chloride of sodium and sulphate of soda. The alkaline carbonates now used by soap manufacturers, are white ash or soda ash. This is obtained by lixiviating the above-mentioned black ash in water, drawing the solution from the insoluble matters, and evaporating to dryness. The residue thus obtained may be used for making lie; but, as it usually contains some sulphide, which, in the production of white soap, is a source of inconvenience, it is necessary for some purposes to calcine this residue at a moderate heat, whereby nearly the whole of the alkaline sulphide becomes oxidized and converted into sulphate.

This ash contains carbonate of soda sometimes to the amount of ninety-five or ninety-six per cent. It is, however, essentially necessary in the production of soap, that the alkali should be rendered caustic—that is, set free from combination by the removal of carbonic acid; as, if it be in chemical union with any other body, it has no decomposing power over the oils or fats. Even if combined with the weakest acids, saponification will not ensue; and the greatest care should, therefore, be exercised in this preliminary process—the preparation of the lies. The process for causticizing is the same in principle for the preparation both of soda and potassa lies. It depends upon the greater affinity of lime than of soda or potassa for carbonic acid, and the decomposition is one of the most simple, thus—

The proportions of soda ash and lime employed vary according to the degree of strength of the soda; similarly with regard to the potassa salt. It is, however, always an advantage to have an excess of lime over the alkaline carbonate, as in the contrary case any undecomposed carbonate is totally lost.

A fact deserving of mention in treating of the preparation of lies is, that in the process of causticizing by means of lime, a portion of the soda appears to enter into some form of combination very difficultly soluble. Mr. KYNASTON, a student of the Editor's, lately examining the calcareous deposit, found it to contain, after being well washed, soda to the amount of five or six per cent. When the deposit, after being dried, is heated to a temperature insufficient to expel carbonic acid, and, after being allowed to cool, is again drenched with water, caustic soda is then removed with great ease, and the deposit may be almost completely deprived of soda. Taking these facts into consideration, the Editor is of opinion that it would well repay the soap manufacturer to collect the lime deposit, VOL. II.

and, after thorough desiccation by exposure to the air, to submit it to heat until the carbonic acid is expelled. The lime now again become caustic, may be used advantageously in the preparation of fresh lie, and the process may be repeated until the deposit becomes highly charged with the impurities of the ash, when fresh lime may again be used for a new process.

Another of those progressive steps manufacturers frequently take, leading to the simplification of operations which previously had been tedious, laborious, and wasteful, has been taken in the soda trade, the especial benefits of which are to be derived particularly by the soap-maker and the public generally. This intellectual advancement consists in preparing *directly* the caustic alkali, by the use of which the soap-maker at once dispenses with a considerable plant outlay, economizes space, expedites the operations of his trade, and effects no little amount of saving in labor alone, compared with the present general practice. Besides the foregoing immediate and apparent advantages resulting in favor of the soap-maker, from the employment of caustic soda prepared *directly*, there are others of much greater importance—namely, the economy of alkali, and the readiness with which soap can be made by the use of lies, the strengths of which are immediately under control, and which cannot be obtained economically on the present causticizing system to which soda ash is submitted, unless at considerable trouble; and even then the lies are not pure, owing to the circumstance that strong caustic alkaline solutions divest carbonate of lime of a portion of its carbonic acid.

The article in question, being in the solid state, is most convenient for transit and storage. It is now prepared largely in some alkali works; MUSPRATT BROTHERS, and HUNTLEY, of Flint, North Wales, manufacture it to a very considerable extent, and the trade is likely to be greatly increased; and the Editor is convinced that its employment would be much more economical to the soap manufacturers than the present method of preparation. It requires simply to be dissolved in a given quantity of water, to produce lies ready for use, and of any required strength. In America it is now largely employed for this purpose, but in England rarely, if at all. Its introduction, though a great advantage to the soap producers themselves, will probably be a matter of as much difficulty as was that of the introduction of the so-called artificial soda, at least as regards the English manufacturer. The method of preparation of this caustic soda will be fully described in a subsequent article. It is of such a nature that it cannot be economically or, indeed, conveniently applied, except where artificial soda is produced to a considerable extent. Being perfectly free from sulphide of sodium, it is especially applicable to the production of white soaps.

Testing the Lie.—That the soap-boiler may be in a position to carry out his method accurately, and to proceed with safety, it is necessary during the lixiviation in the ash tubs, and whilst boiling the fat, that he should be able at any moment to ascertain correctly the strength of the lies. For this purpose specific gravity bulbs, or the *hydrometer*, is used. In this country Twaddell's hydrometer is most commonly employed.

The indications of such an instrument are in no kind of connection with the chemical nature of the fluid; and as the graduation is perfectly arbitrary, nothing more can be established by its application than a comparison of the densities of different liquids. As, however, a correspondence has already been established between the degrees of the hydrometer and the specific gravities, and it is also known what proportions of potassa and soda correspond to the specific gravity of different solutions, the hydrometer may be used as a means of ascertaining the amount of alkali present. The degree indicated by Twaddell's hydrometer, multiplied by five and added to one thousand, expresses the specific gravity of the fluid. A lie testing 27.50 Twaddell, for instance, has a density equal to 1.138, which is equivalent to 15 per cent. of potassa or 12.8 per cent. of soda, always supposing the lie to contain no other matters or salts which might also affect the specific gravity. This, however, is never the case with soap-boilers' lie, so that the indications are only approximations with reference to the amount of alkali, or even may be altogether fallacious. Still they are useful in a variety of ways, and are, indeed, indispensable. The practitioner is able with this instrument to follow the diminishing strength of the liquid flowing from the ash tubs or vats, and to form a just estimate of its value, when, at the same time, a test with acid proves the absence of carbonic acid. But even in the process of soap-boiling itself, the test of the lie afforded by the hydrometer, combined with the personal experience of the workman, is a clue by which he is enabled to judge whether the proper strength has been attained; knowing as he does what degree the hydrometer ought to indicate from any particular soda or potassa lie for any particular purpose. The more or less caustic taste of a lie is also a test much depended on by many soap-boilers.

SAPONIFICATION.—Oils and fats themselves are neither soluble in water nor miscible with it; but nearly all are made so by union with alkali. The process of effecting this combination is termed *saponification*, and the compound produced is *soap*—hard soap when its base is soda, but more or less soft when potassa is the alkali present. The properties and composition of the different kinds of oil and fat, as well as their behavior under the influence of various reagents, have been fully discussed in a separate article. It is, however, necessary in considering the theory of saponification, again to notice the constitution of these bodies in its bearing upon their conversion into soap. The fixed oils, as well as the animal fats, are composed for the most part of certain proximate principles, of which stearin, margarin, and olein are the most abundant. Some oils, as for instance palm oil, have constituents peculiar to themselves; but as they are quite analogous to olein, and other bodies above-mentioned, in their chemical constitution, and consequently similar in their relation to alkalies, these will serve as examples.

In animal fats stearin is usually the most abundant constituent; margarin more especially characterizes the vegetal and human fats; olein is present in both, though varying in its nature in different kinds of oil.

Stearin, margarin, and olein, however, are not free

uncombined bodies, but positive compounds, each of its respective acid with a base, termed *oxide of glyceryl*, the hydrate of which is glycerin. Thus, though the base is the same in all, the acid constituent in each of the three is peculiar. The acid in stearin is termed *stearic acid*; that in margarin, *margaric acid*; and that in olein, *oleic acid*. Stearin, margarin, and olein have, therefore, a saline constitution, and may be respectively regarded as a stearate, margarate, and oleate of oxide of glyceryl. When brought into contact with a free alkali, or a metallic oxide in presence of water, these fatty principles undergo decomposition; the alkali, or metallic oxide, being a more powerful base, seizes the oily acid, and a stearate, margarate, or oleate of potassa is formed, as the case may be. These latter compounds, when mixed with a solution of a more powerful acid, such as the mineral acids, or even of the stronger organic acids, as oxalic, tartaric acid, *et cetera*, are decomposed, a salt of the base with the acid employed being produced, while the oily acids are set free, and at the instant of separation combine with a certain proportion of water. The oxide of glyceryl, liberated from the fatty principle by the action of an alkaline solution, also at the moment of separation enters into combination with a definite proportion of water, the product being glycerin, which, owing to its sweet taste, and the source whence it is procured, was originally termed the sweet principle of oils. It will now be more easily understood that the oils or fats, or the principles of which they are composed, are themselves incapable of *direct* combination with the alkalies, or other bases; or, in other words, the mixture of a fat or oil with an alkali, does not occasion the formation of soap. On the addition of water, however, with which the base of the fatty principle may combine, saponification ensues immediately. Previously to the admirable investigation of CHEVREUL, to whom chemists are indebted for a knowledge of the composition of oils and fats, and their peculiar properties and behavior, the presence of water in the process of saponification was supposed to occasion a change proportional to its elements, converting the stearin, margarin, and olein into new bodies, which from their acquired acid properties were termed adipose or saponic acids; the peculiar unsaponifiable body glycerin being left behind as an incidental product. Hence, what are now known to be positive compounds of a fatty acid with the base of glycerin, were considered as altered in ultimate composition by the action of water and alkali. This view is now known to have been fallacious, and it has been conclusively demonstrated that the acids exist ready formed in the fats, and are separated from the base-oxide of glyceryl, in accordance with that law which determines the power of stronger bases over weaker ones.

Thus, therefore, when solution of potassa or soda is boiled with oils, the fatty acids are abstracted, and the eliminated oxide of glyceryl, uniting with water, forms glycerin. And thus it is explained why the fatty acids separated from oil, estimated together with the glycerin, always exceed the weight of the oil or fat submitted to decomposition—the excess being due to the water entering into combination both with the glyceryl base, and with the fatty acids. The following diagram

will render the decomposition that ensues, when an oil is saponified, much more intelligible :—

Substances employed.	Composition.	Products of decomposition.
Fats or oils, namely, stearate, margarate, oleate, <i>et cetera</i> , of oxide of glyceryl.	{ <div> Stearic acid, Margaric acid, Oleic acid, + Oxide of glyceryl, </div>	Stearate, margarate, and oleate of potassa or soda, that is, soap.
Potassa or soda, Water,		
		Hydrated oxide of glyceryl, that is, glycerin.

Soap, therefore, it will be observed, does not result from a direct union of the fatty matter with the alkali; a further proof of which is seen when the soap obtained as above is decomposed by the agency of a stronger acid. It will be found that the acid decomposing the soap, by seizing its alkaline base, leaves the fatty material in a totally different state to that in which it existed when originally added. It is now found to possess acid properties, and to unite much more readily with alkalies; or, in other words, to be more easily saponified. This latter property is accounted for from the fact that, being in an uncombined state, the acids have no base to overcome, as was the case in the first instance. In all saponifiable fats, the same reaction ensues, though the soap produced contains different acids, according to the kind of grease or fat employed. Thus, in the case of palm oil, the soap consists for the most part of *palmitate* of soda or potassa. When spermaceti is used, the soap produced consists of *cetyl-ate* of potassa or soda, and instead of glycerin, an analogous body termed ethal is found in the mother-liquor. By far the greater majority of fats, however, yield when treated with alkalies, soaps containing only stearate, margarate, and oleate of potassa, if a soft soap, and of soda in the case of hard soaps. Resin, though employed in the manufacture of soap in the place of fixed oil or fat, is not to be considered analogous to a fat in its chemical constitution, or to be capable of forming with an alkali a proper soap by itself. Resin contains neither oxide of glyceryl nor oxide of cetyl, nor any equivalent for these substances, but is an indefinite mixture of three distinct bodies possessing well-marked acid properties; and hence named *sylic*, *pinic*, and *colopholic* acids, each of which is capable of entering into combination with alkalies, and of readily dissolving in alkaline solutions, though totally insoluble in pure water.

For the complete saponification of fats or oils, an excess of alkali is requisite, and is so much the more willingly employed, as it can be removed again without difficulty. The production of soap is by no means a momentary process, nor can it be done with the same exactness or rapidity as the decomposition of an ordinary salt. On the contrary, the manufacture consists of a number of stages, and these occupy a considerable length of time from the first mixing of the fat with the alkali, when a sudden emulsion is produced, to the formation of soap ready for use, or even to that point when the whole of the alkali is saturated with fatty acid. Acid salts are first produced with the oily acids, and these hold the remainder of the fat in solution, or in a state of division, until it also is able to combine with alkali, and transform the acid into neutral salts, or into finished soap. This reaction may easily be observed, if the fat is boiled with one-half the required quantity

of alkali; the whole of the oil is in such case dissolved, but the solution becomes turbid on cooling, and when water is added, and the mixture again boiled, unsaponified fat separates, showing that this had only been retained in the fluid by the stearate or margarate of the alkali that had been formed.

HARD AND SOFT SOAP.—Soaps are divided into two classes, differing from each other in the material from which they are produced, and are distinguished by the names *hard* and *soft soap*. Hard soaps are made from fats, or vegetal fat oils, and soda; for soft soaps, the oleaginous material is usually a fish oil or vegetal drying oil, and the alkali, potassa. Hard soaps may, however, be made with potassa, provided a solid fat be employed; but soda soaps are invariably harder than potassa soaps, the unctuous material being the same. The hard soaps of animal fats are either white or marbled, and are particularly applicable for washing the finer articles of dress, the soft soaps being more caustic than the solid soda soaps. Of the hard soaps of commerce those made with oils, with the exception of palm-oil, are mixtures of margarate and oleate, with only a small proportion of stearate of soda; those made with animal fats are mixtures of stearate, margarate, and oleate of soda. On the continent, and wherever wood is abundant, potassa is frequently introduced in admixture with soda in the production of hard soaps.

PROPERTIES OF SOAPS.—Potassa and soda soaps are readily soluble in hot water and alcohol; the addition of a quantity of water to the aqueous solution produces a precipitation, the neutral salts of stearic and margaric acids decomposing into free alkali, which remains in solution, and acid stearate and margarate of alkali, which precipitates in the form of pearly, crystalline scales. Potassa soaps are more soluble in water than those containing soda. Stearate of soda may be regarded as the type of hard soaps; in contact with ten times as much water it suffers no striking change, while stearate of potassa under the same circumstances forms a thick paste, or a viscid solution. In these respects the margarates of potassa and soda closely resemble the corresponding stearates. Oleate of soda is soluble in ten parts of water, and oleate of potassa in four parts. The latter forms a jelly with two parts, and possesses such a strong affinity for water, that one hundred parts absorb one hundred and sixty-two when exposed to a humid atmosphere. It follows, therefore, that soaps are soft in proportion to the oleates, and hard in proportion to the stearates and margarates they contain; so that the softness or hardness of soap is not solely dependent upon the base that is employed.

Soap of Commerce—that is, stearate, margarate, or oleate of alkali—is never dissolved by cold water without decomposition. The neutral salts are resolved into alkali, which dissolves, and into an acid salt, which is

precipitated. The same decomposition occurs when hot solutions of soap—particularly of dilute—are cooled. According to CHEVREUL, who particularly investigated this decomposition in the case of stearate of potassa, when a solution of this neutral salt—2 KO, St—is cooled, one-fourth of its potassa remains in solution, and a

Acid stearate of potassa, after being separated from the liquid as above, and treated with a thousand parts

mixture of neutral with acid stearate of potassa is separated. If the same salt is dissolved in five thousand parts of cold water, the acid stearate—KO, St—is alone precipitated in the form of pearly scales, and half of the potassa remains in solution according to the subjoined equations:—

The occurrence of these decompositions, which ensue equally with the margarates and oleates of potassa and soda, as with the stearates, affords an easy explanation of the appearance of the whitish turbidity always produced when soap is dissolved in even the purest water, and show, at the same time, that the alkalinity of soap-suds is solely due to the liberation of caustic potassa or soda; and this it is that affords the possibility of removing fatty impurities in water, which is the sole object of washing with soap.

It is of the utmost importance to the soap-boiler that he be well acquainted with the physical comportment of soaps with solutions of different salts, as, for instance, with chloride of sodium, carbonate of soda, the corresponding potassa salts, chloride of ammonium, and various others. These although not absolutely essential to the formation of soaps are very much concerned in the separation of the foreign matters that render hard soap impure; and are also useful to impart to it the proper amount of water. In practice, a solution of chloride of sodium is always employed for this purpose. The peculiar behavior of soap with a solution of this salt is thus described by LIEBIG:—If a piece of common hard soap be placed in a solution of salt at ordinary temperature, it floats upon the surface without ever being moistened, and if the liquid be heated to boiling, it separates without foam into gelatinous flocculæ, which collect on the surface, and upon cooling unite into a solid mass, from which the solution flows off like water from fat. If the flocculæ be taken out of the hot fluid, they congeal on cooling into an opaque mass, which may be pressed between the fingers into fine laminæ without adhering to them. If the solution is not quite saturated, the soap then takes up a certain quantity of water, and the flocculæ separate through the fluid on boiling. But even when the water contains one four-hundredth part of common salt, ebullition does not produce solution. If the soap is boiled in a dilute and alkaline solution of salt, and suffered to cool, it again collects on the surface of the fluid in a more or less solid state, depending on the greater or less degree of concentration of the solution; that is, on the quantity of water taken up by the soap. By boiling the dilute solution of salt with soap for a considerable time, the

of hot water, is again decomposed into neutral stearate of potassa, and a still more acid stearate, as follows:—

aqueous flocculæ intumesce, and the mixture assumes a foamy appearance, but still they are not dissolved, as the solution separates from them. The flocculæ, however, have become soft and pasty, even after cooling, and their pastiness depends on the quantity of water they have imbibed. By still continued boiling this character again changes, and in proportion as the water evaporating renders the solution more concentrated, the latter again extracts the water from the flocculæ; the liquid, however, continues to foam, but the bubbles are larger. At length a point is attained at which the solution becomes saturated; the larger iridescent bubbles formed just before disappear, and the liquid continues to boil without froth; all the soap collects as a translucent mass on the surface, and now the solution and soap cease to attract water from each other.

If the plastic soap be now removed and cooled, while the solution is pressed out, it becomes so solid as scarcely to receive an impression from the fingers. In this state it is called *grain soap*. The addition of salt, or its solution, to a concentrated alkaline menstruum of soap in water, precipitates the soap in gelatinous flocculæ, and the mixture behaves precisely as solid soap boiled with a dilute solution of salt. Carbonate of and caustic potassa act exactly as salt in separating soap from the alkaline fluid. The application of these facts to the manufacture of soap is obvious. The fat is kept boiling in an alkaline lie until all pasty matters disappear; but the lie should have only a certain strength, so that the soap may be perfectly dissolved in it. Thus tallow may be boiled for days in a caustic potassa solution, of specific gravity 1.25, without being saponified. If the lie be stronger a partial saponification ensues; but being insoluble in the fluid, the soap floats on the surface as a solid mass. By the gradual addition of water with continued boiling, the mass at a certain point becomes thick and clammy, and with more water an emulsion is formed; on continued heating, this becomes perfectly clear and transparent, if a sufficient quantity of alkali be present. In this state it may be drawn out into long threads, which on cooling either remain transparent, or are milky and gelatinous. As long as the hot mass, suffered to drop from a spatula, exhibits a milkiness or opalescence, the boiling is continued, or

more alkali added. When excess of alkali is present, the milkiness arises either from imperfect saponification, or want of water; the former is known by dissolving a little impure water, which becomes perfectly clear when the whole is saponified.

If the lie contain lime the mixture is also turbid, but the addition of an alkaline carbonate causes the turbidity arising from this cause to disappear instantly. In order to separate the soap from water, free alkali, and glycerin, a large quantity of salt is gradually added to the boiling mass, waiting after each addition till that portion is completely dissolved; the first addition increases the consistency of the mass, while each successive portion renders it more fluid, till it loses its adhesive character, and drops from the spatula in short thick lumps. As soon as the congelation is complete; that is, when gelatinous flocculæ separate from a clear watery liquid, the fire is extinguished, the soap allowed to collect on the surface, and cooled either on the liquid, or ladled out and allowed to get solid. In being separated by means of salt from a very dilute solution, soap suffers an alteration in composition, the soap so thrown down being a bistearate, bimargarate, or binoleate of the alkali, instead of the neutral compound originally in solution; but when the solution is of moderate strength, the soap is separated unaltered in composition. The same results as those obtained by the use of common salt are also produced, although in a less

energetic manner, by chloride of potassium, carbonates of the alkalies, sulphate of soda, acetate of potassa, and chloride of ammonium. Of these, sulphate of soda and chloride of potassium have but a very slight action. Concentrated caustic lies also separate soap from its solution, in the same manner as with common salt; in weak caustic lie, on the contrary, soap is perfectly soluble. On this account soap-boilers, especially at the commencement of the operation, except in the case of cocoa-nut oil, always use weak lies, as the stronger would prevent the necessary amount of contact amongst the ingredients, and very much retard the process of saponification. Not only all foreign matters other than soaps, but also the base of the oils—glycerin—is completely separated from soap by means of caustic or saline solutions, in which it is perfectly soluble. The separation of the small quantities of earthy and metallic soaps, always formed during the process of saponification by means of impure alkalies, requires a distinct operation, termed the *fitting* process, which will be presently alluded to.

The Caldrons.—The boilers or caldrons used in the soap manufacture are formed of cast-iron or wrought-iron plate. Their capacity varies according to the quantity of soap to be produced at each operation. The pan or kettle is fixed in the brickwork, and so built round that the heat acts solely on the bottom. Before the repeal of the soap duty, the waste lies were required

Fig. 502.

to be pumped out at the top, through the mass of soap. Now it is usual to withdraw these from the bottom, by means of a pipe fixed to the boiler. Fig. 503 is a section of the arrangements. The pans are usually cast with a flange at the upper rim, so that if necessary the boiler may be enlarged by adjusting a hollow cone

of wood, iron bound, and which is termed the *curb*. It may extend as high as desired, and should be surrounded with mason-work as the rest of the pan. In some manufactories the boiling of the soap is accomplished by means of steam, either conducted directly into the materials in the boiler, or when a too high

temperature is not desirable, by applying the steam to the outer surface of the caldron. The application of steam is a method of communicating heat to the caldrons,

Fig. 503.

far preferable to the old method of placing the boiler directly in contact with the fire. Not only is there a great saving of fuel, but less attention, and, consequently, fewer hands are required, while the facility of arresting ebullition at any desired moment is of great importance. In the annexed representation—Fig. 502—are shown three caldrons, A, A, A. The main pipe or feeder, *c*, is attached to the boiler, *w*, which is stationary, and generally placed against the wall immediately above the kettles or caldrons. These latter are partly of iron and partly of wood, the upper portion or *curb* being wood, well hooped round by iron rings, and the lower portion of cast-iron, and so shaped that the worm can lie closely to the sides, and that the blow-pipe can fit upon the bottom. The cock, *i*, is for the withdrawal of the spent lies. The pipe, *l*, serves when necessary to communicate additional heat to the contents of the pan, and is useful also to agitate the mass. In some manufactories the boiling caldrons are made wholly of wood, well fastened by iron clamps.

MANUFACTURE.—Hard Soaps.—The process of soap-making varies in some particulars according to the kind of oil or grease to be saponified, though the general method is the same for all. The lies or solutions of caustic soda having been prepared as previously directed, the whole quantity of unctuous material to be saponified at one operation is usually introduced into the boiler at once, and for every ton, from a hundred and fifty to two hundred gallons of caustic liquor of specific gravity $1.090 = 18^\circ$ Twaddell are added, and the whole is gently heated to ebullition. After boiling for an hour and a half or two hours, the whole forms a viscid emulsion, capable of being drawn out into clear threads. The soap now produced is in solution in the water, and requires to be separated before the spent lie can be withdrawn, and to complete the saponification, a fresh one applied. For this purpose a sufficient quantity of common salt is added, which, dissolving in the liquid, causes the soap—which, as previously observed, is quite insoluble in a strong solution of chloride of sodium—to rise to the surface.

When the soap paste has remained in the boiler a sufficient length of time to have become partially cool, it is ladled out into buckets or pails, conveyed to the frame-room, and poured into the frames to solidify. These frames or *sesses* consist of a pile of rectangular inclosures, measuring internally about forty-five inches

by fifteen inches. They should be very smooth, and so jointed as to fit closely together. When piled one upon the other, to the height of three or four feet, they form a tight square well fitted to receive the boiled soap paste. They are tightly bound together by clamps and screw rods. Cast-iron frames, as a substitute for the above, in the manufacture of yellow soaps, are of late introduction. These latter are formed of five rectangular plates, one for the bottom, two for the ends, and two for the sides, so arranged and fastened together as to form a well or reservoir of the same length and breadth as the wooden frames, and about five feet in height. These frames are put together and taken to pieces much more easily than those of wood, and the good conducting power of the iron considerably accelerates the cooling and solidifying of the soap. If the soap is allowed to solidify in the state in which it is run into the frames, it has a rough granulated texture, and is extremely hard. It is therefore usual to mix a small quantity of water with it in the frame, and afterwards agitate the mixture with a wooden *paddle* or *crutch* until nearly cold. By this means it acquires a finer grain, and is not nearly so hard.

The soap having become cold and dry, and in a state to be removed from the frames, which may be known by gentle pressure of the finger making no impression, the iron screw rods which bind the frames together are removed, and each frame is lifted off the soap, which is left a compact mass of the size of the interior of the frame. This mass is then marked round with a kind of iron toothed *scribe* or *dentier*. This instrument is shown in Fig. 504. The teeth are near or distant from each other accordingly as the blocks

Fig. 504.

Fig. 505.

are desired of small or large size. The mass is then cut by means of a wire, as shown in Fig. 505, into slabs, and these are again sub-divided into bars. These bars are then removed to the drying-room, and piled upon one another crossways, interstices being left for the circulation of air, to facilitate the drying.

The process of the manufacture of soap, though constant in principle, varies in detail in different countries. The following is the method pursued in the United States, as described by MORRIS:—The strength of

the lie employed differs accordingly as the oil to be saponified is richer in olein or in solid constituent. The operation is commenced by pouring the lie into the boiling caldron to a third of its capacity. This is then heated to ebullition, and the oil is now poured in. The reaction is such that a magma is immediately formed. The proper formation of this magma is considered to be the most delicate and important part of the whole process, and if badly managed, a much greater quantity of lie is required to form the same weight of soap than otherwise would be. After pouring in the oil, the heat is decreased by opening the doors of the furnace, and when the mixture of oil and lie is complete, if necessary a further quantity of weak lie is added gradually, and with constant stirring during the addition, so as to insure thorough contact. The mass should remain homogeneous; the oil should neither rise to the surface nor descend to the bottom. If oil should present itself, it is then necessary to add more strong or weak lie, according to the capacity of the caldron. If the lie is in excess, a further quantity of oil must be added; always stirring briskly upon any addition of new material. The operation requires from eighteen to twenty hours for completion. It may, however, be greatly accelerated by throwing in the scrapings or the waste of soap already made. An excess of soda is recognized by the liquidity and transparency of the paste. If the oil is in excess it rises to the surface. The presence of a large proportion of common salt in the soda, also prevents more or less the proper formation of the magma. When this is the case to any considerable extent, the use of soap scraps is indispensable. The next step in the process is the removal of the large quantity of water which was required for the ample saponification of the fat. This is effected by the addition of lies containing common salt, and afterwards boiling the mixture from fifteen to twenty hours, constantly stirring during ebullition. When the mass opens in different places, the separation is complete. The fire is withdrawn, and the whole is now allowed three or four hours' repose, after which the settled waste lie is drawn off. A further quantity of lie, charged with common salt, is now added, and the mixture is gently boiled; being careful to remove from the sides of the caldron any adhering soap, so that all portions may be in contact with the lie. The mass now acquires more consistence. After some hours' repose, the settled waste lie is again withdrawn. Lie of specific gravity $1.10 = 20^\circ$ Twaddell is poured in, and the mixture is again boiled; by this it acquires a still greater consistence. After continued boiling for about three hours it is allowed to deposit, and the waste lie is again drawn off. This operation is repeated once more, but with strong lies, being careful to stir the paste while being heated, so that the whole may form a homogeneous mass, and allowing only a gentle ebullition. The soap at this stage begins to acquire firmness. The boiling with lie several times successively, serves not only to complete the saponification, but to wash and purify the soap. That it may be perfect, it is necessary to repeat the operation four or five times. As soon as complete, the fire should be withdrawn, and the mass allowed repose to settle and become somewhat cool,

and then ladled out and conveyed in buckets to the frames.

WHITE SOAP—CURD SOAP.—The unctuous material employed in the production of this soap may be tallow or lard, or olive, or well-bleached palm oil, or mixtures of these in almost any proportion. To produce one ton of soap, from ten to fourteen hundredweight of tallow or olive oil are required. The process of saponification is conducted as above described, with but slight variation, attending more particularly to the complete removal of the *alumino-ferruginous* impurities of the lie, which otherwise impart to the soap a coloration more or less intense. Their removal is effected by boiling the soap several times with fresh lies, or by thinning out the soap with a little lie, and applying gentle heat, then covering the caldron carefully and allowing it to settle. The upper strata of soap is afterwards ladled out and run into the cooling frames. The average composition of ordinary white tallow soap is—of alkali one part, of fatty acids about nine parts, and five to eight parts of water. In England by far the greater quantity of curd soap produced is made from tallow or mutton suet and soda only. Some manufacturers, however, substitute for one-fourth of the tallow as much lard or olive oil, and a soap is produced greatly superior in quality, and less liable to change by exposure. Soap made solely of tallow is, besides, inconveniently hard, and very difficult of solution. In France, and on the Continent, when tallow is saponified, olive oil is always added in the proportion of twenty to twenty-five per cent. of the oleaginous material. In England lard is not unfrequently used as the softening agent; and when applied in about the same proportion answers every purpose, while it has the advantage over olive oil, that it does not detract from the whiteness of the soap. The advantages gained by the addition of lard to olive oil or to tallow may be summed up as follows:—The soap remains unaltered for a longer period, does not emit the disagreeable odor of tallow, and the saponification is more perfect, as the excess of olein in the lard or oil compensates for the large amount of stearin in the tallow, thus inducing a more ready and perfect union of the alkali and oily acids. English white or curd soap is largely used by the cloth manufacturers of Yorkshire, and the lace and stocking bleachers of Nottingham. Tallow is not saponified to a very considerable extent on the continent; but in its stead, olive oil mixed with about one-fifth of rape oil is used in the manufacture of hard soaps. This addition of rape oil is always resorted to, because olive oil alone yields a soap as hard and compact, and as difficultly soluble, as soap made wholly of tallow and alkali. This, however, is not the case with rape oil, and other oils of a similar nature—that is, such oils as become thick and viscid by exposure; experience having demonstrated, though the reason is as yet unknown, that the oils which turn viscid the soonest by exposure, yield with soda softer soaps than those made with oils which, like olive oil, remain long limpid under the influence of the air. The admixture of rape oil with olive oil has therefore the effect of modifying the degree of hardness of the soap, just as when lard is saponified in conjunction with tallow.

YELLOW SOAP.—This variety of soap differs from the preceding and other kinds, inasmuch as a considerable quantity of *resin* enters into its constitution. This substance, as previously observed, is capable of entering into combination with the alkalies, to produce a detergent compound soluble in water. Besides the resin, or common fat, or inferior tallow, palm oil is also used to a considerable extent. The usual proportion of palm oil and resin are three and a half parts of the former to one of the latter; sometimes the proportion of resin is still greater, and the soap produced is then soft and dark colored. When the saponification of the oil is nearly complete—that is, at the last charge of the lie—the resin is introduced in a state of coarse powder, and well mixed with the soap by agitation. The mixture is then boiled for some hours; a small quantity of lie being added from time to time, if necessary, to preserve an excess of alkali until the soap is completely formed, when the lie may be withdrawn and one or two waters, or else weak lies, applied successively with agitation for the purpose of washing and purifying the soap. The resinous scum being removed for another operation, the soap is conveyed to the iron frames to solidify. Yellow soap usually contains, to one part of soda, from ten to eleven parts of oily acid and resin, with from twenty-four to fifty per cent. of water. If it contain a large proportion of water, it has just the same appearance as when it contains only a small proportion. When anything like fifty per cent. is present, it has been added while the soap was in the frames, for the purpose of fraud. If tallow or other grease be employed in the manufacture of yellow soap, instead of palm oil, the following is the mode of procedure:—Two thousand pounds of the oil or fat, six hundred pounds of resin, and from a hundred and fifty to a hundred and seventy-five gallons of soda lie of specific gravity 1.075 to $1.150 = 15^{\circ}$ to 30° Twaddell, are run into the boiler, and when the whole is melted, the mixture is heated to ebullition, stirring carefully all the time to prevent the resin adhering to the bottom and sides of the caldron. Should the mass begin to swell out, the heat must be decreased. The first boiling should be continued not more than two or three hours, on account of the facility with which the combination of the fat and alkali is effected. After six hours' repose the exhausted lie is withdrawn, and fresh substituted, and the whole is again boiled for three hours or more. After another repose of six hours, again draw off the spent lie, and renew it with fresh. The ebullitions are thus continued, day after day, until the soap has acquired a proper consistence, which may be ascertained by taking a small portion, and when cool, squeezing it between the thumb and finger. If hard thin scales are formed, it is finished, and after having boiled briskly the fire is removed; but if greasy, clammy, and soft, it is not perfect, and it is necessary to add more lie and reboil. The soap is now to be cooled by adding three bucketfuls of lie, and after two hours the liquor is withdrawn. Six or eight bucketfuls of water are now added, and the whole is again briskly boiled, stirring constantly until the soap is melted. A little of the boiling paste is now removed on a wooden spatula, and if it run clear from the lie,

more water is added, and the boiling is continued. If it should not run, too much water has already been added, and a half pailful of strong solution of salt must be thrown in.

The most delicate part of the operation is that of boiling, and it therefore requires particular attention. That it may be complete, the soap should, when a portion is taken on a spatula, and the latter is held in an oblique position, shake and disperse tremulously, as would a body of gelatinous consistence. Then the fire may be withdrawn, and the soap considered as finished. In France yellow soap is produced by a similar process as the other kinds of common soap, adding at the commencement of the operation fifteen to twenty per cent. of resin. Some manufacturers make a soap with but five to ten per cent. of resin, and this being lower-priced than soap made entirely of grease, has a more extensive sale, and is preferred especially for domestic purposes. By its property of dissolving more readily in sea-water than other soaps, it is also well adapted for use on shipboard. The common brown soap is made as the preceding, but by using a greater proportion of resin, and substituting for the tallow, either in whole or in part, the common kinds of grease, such as soap fat, bone fat, *et cetera*.

MOTTLED SOAP—MARBLED SOAP.—In the manufacture of this variety of soap, the same kinds of materials are used as for white soap, and its different appearance arises from the different mode of treatment of the soap, after the completion of saponification. By a reference to the general process of soap-making given above, it will be observed that even after the complete formation of soaps, that is, when the whole of the oil or fat used is decomposed, and the oily acids have entered into combination with alkali, the soap still requires further treatment before it is brought into a marketable condition. It exists now in the form of immovable globules, and it is necessary to cause these to coalesce into a homogeneous mass. This is effected by a process termed *fitting*, which consists in the fusion of the contents of the boiling caldron in a weak lie, or in water, and afterwards boiling the whole for a longer or shorter period, according to the kind of material operated upon, the mass being prevented from boiling out of the copper by dashing shovels into it, so as to break the froth and favor evaporation. During this process in making white or curd soap, the more or less colored impurities of the materials termed *nigre* or *nigger* fall to the bottom; but in making mottled soap, the mixture is left in a thick or viscid state, so that the impurities cannot subside, and is transferred to the frames in this condition. To produce a good marbled soap, it is necessary that this latter operation be very carefully conducted; as, if too great a quantity of liquid be added, or if the mixture of soap and water or weak lie cools too slowly, all the coloring matter falls to the bottom, leaving the upper stratum of soap perfectly white, while, on the other hand, if it becomes too quickly cold, the soap remains in the granular condition. THÉNARD compares the separation of the coloring material to a kind of crystallization, and MORFIT ascribes the result to the formation of an *alumino-ferruginous soap*, and the lesser solubility of this at a lower temperature. The

lower veins in mottled soap appear to be due to the presence of an exceedingly minute trace of sulphide of iron, derived from the last service of lie, in which it exists in solution as a double sulphide of sodium and iron. As a perfectly colorless lie, apparently free from every trace of iron, will produce mottling if allowed to separate slowly from soap, it has been questioned whether iron is really the coloring agent; but, as noticed by PARNELL, this seems to be proved from the fact that the ash which remains after the calcination of the brown parts of such soap, affords to reagents a sensibly larger quantity of iron than the white parts of the same sample of soap. Granting that the lie used may be free from iron, which, however, is very rarely the case if an alkaline sulphide be present, this has a solvent action on metallic iron, and will therefore take iron from the pans or boilers used; and even supposing the lie to be free from alkaline sulphide, it becomes a matter of doubt whether, in the process of boiling, a portion of sulphate may not be reduced to the state of sulphide by prolonged contact with the organic matter. In some cases—and in such, iron must be present in some form or other—the mottling is produced, or at least the proportion is increased by sprinkling on the surface of the soap, after being boiled with the last service of lie, a small quantity of very strong sulphuretted lie, which produces the mottling by filtering slowly through the mass of soap. At Marseilles and other places where olive oil is used in making soap, a quantity of sulphate of iron is added; in which case the mottling is produced, both by the black sulphide of iron, and by the oxide of iron—the red portion—which latter combines with fatty acids, producing a true ferruginous soap. The quantity of copperas requisite is about eighteen ounces to four hundred and fifty pounds of oil or fat. It is added first mixed with weak lie, and should be poured in during the coction of the soap, and before it has acquired too much consistence. When the soap is ladled out of the boiler, it is of a uniform slate tint; but as it becomes cool, the metallic portion separates into nodules, and by the trickling of the excess of lie through the mass, they assume those forms to which the term *mottled* is applied. By varying the proportion of sulphate of iron a tint is produced of a lighter or darker hue. Soaps containing this have exteriorly a rusty color, owing to the sesquioxidation of the iron at the expense of atmospheric oxygen, and this shade may be deepened by the addition of venetian red, or colcothar, into the particular tint to which the French apply technically a term signifying *hidden red*, and which upon the deep blue produces the appearance of marble, as seen in the variety known as *castile soap*. This peculiar tint may be communicated as well before as after the true marbling; for which purpose it is necessary to thin out the colcothar with water, and in adding it to incorporate it well with the soap. Generally, in the preparation of mottled soap, less care is exerted in the choice of materials than for white soaps, and the heterogeneous mixture of fatty substances, known as *kitchen stuff*, usually forms one of the materials.

COCOA-NUT OIL SOAP.—Cocoa-nut oil is very easy to saponify, and is used to a considerable extent in

the manufacture of white soap, as well *per se*, as in admixture with other oils and fatty matters. The disagreeable odor of this oil is removed most effectually and conveniently by boiling in a wooden vessel by means of steam, with a mixture of six pounds of sulphuric and twelve of hydrochloric acid to each tun of oil. The oil so purified is heated in the boiling caldron, with the addition of a portion of olive or some other readily saponifiable oil or fat, and the soda lies are gradually introduced in the usual manner. Towards the conclusion of the process of saponification, a quantity of caustic potassa lie is thrown in, and the boiling is continued as long as may be necessary. The soap thus formed requires, for its separation from the lies, a much larger proportion of salt or other saline matter, than the soaps formed of tallow, palm oil, or olive oil. Otherwise the process of separation is the same as for other soaps. Pure cocoa-nut oil soap, by the usual method of saponification, can only be obtained by the use of a very large quantity of common salt, and then contains so very little water, or is so extremely hard, that it cannot be cut with a knife. On this account the usual mode of proceeding is not followed, in the production of this soap. The principal distinction between cocoa-nut oil and other oils and fats is, that while the latter are most readily saponified by weak lies, cocoa-nut oil is quite unacted upon until the lies have obtained a considerably higher degree of concentration; saponification then suddenly commences, and proceeds with extraordinary rapidity. Only the strongest soda lies are employed in the production of this soap, and by taking pure and perfectly caustic lie, the use of salt in purifying the soap is dispensed with. Pure cocoa-nut oil hardens much too quickly to exhibit any distinct formation of curd, and is consequently incapable of marbling of itself; it is very white, translucent, exceedingly light, and forms a good lather, but has always a more or less offensive smell.

An important property of cocoa-nut oil is its power of combining with more water than can even be incorporated with tallow soap, and this property frequently leads to dishonest practices. Cocoa-nut oil actually produces no greater quantity of soap than an equal weight of tallow; but the soap from the former can easily be made to absorb one-third more water or lie, and, at the same time, exhibit no want of consistence or softness, as would be the case with other soaps. The more rancid cocoa-nut oil be, the more readily is it saponified.

As previously remarked, cocoa-nut oil is not usually saponified alone, but is added to other oils for the purpose of producing quickly solidifying soaps containing a large proportion of water. When equal parts of cocoa-nut oil and tallow are used, the soap has the smell of common tallow soap. The boiling is continued until a specimen exhibits the proper consistence under the thumb. Tallow itself could not be saponified under the same conditions; but the saponification begins with the cocoa-nut oil, and the tallow is then saponified by means of the presence of the cocoa-nut oil soap. The different varieties of this soap are marbled artificially. The blue or red coloring matter is rubbed up with a little of the soap, or better, with a separate portion

of good cocoa-nut oil soap, until the whole acquires a red or blue color. This is then placed in alternate layers with the colorless soap; and by stirring the mass together streaks and veins are produced in all directions.

MARSEILLES SOAP.—This variety of soap is produced by the saponification of olive oil alone. The process does not materially differ from that described for white soap. The duration of the operation is longer or shorter according to the quality of the oil. Some manufacturers use, in the fabrication of this soap, a certain proportion of poppy oil with the olive oil; and the addition is rather beneficial than otherwise, as the soap produced is less hard, and consequently more easily applicable to detergent purposes. It is at present manufactured on a considerable scale in this country.

An improvement on the old method of soap-making was invented by DUNN, and has been already alluded to. It consists in the application of streams of air to the materials, whilst in the course of saponification. The air is forced below their surface by means of a pump; and the saponification is said to be greatly accelerated, and the process otherwise much improved. The following is the method as stated by MORFIT:—Into each of the ordinary boiling caldrons a circular ring of pipe of about one and a half inch bore, and perforated with small holes, is fixed in the well of the kettle, just below the flange or joint, keeping it sufficiently off the bottom to allow a stirrer to be used to scrape the bottom when necessary. The pipe is supplied with atmospheric air from a cylinder blast, or other suitable forcing apparatus, and is connected with the latter by means of a pipe attached thereto, and rising up to the top of the kettle, where it is furnished with a stopcock and union-joint, for the purpose of connecting or disconnecting the parts of the pipe within and without the copper. For a clean yellow soap ninety gallons of lie of specific gravity $1.14 = 28^\circ$ Twaddell, are run into the caldron. The fire being kindled, the caldron is charged with two thousand and fifty pounds of grease; and as soon as the lie is at or near the boiling point, the blast is commenced, keeping up a brisk fire so as to continue the materials in the kettle as near ebullition as possible. When the lies are exhausted, an additional quantity is gradually added until the grease, oil, or fatty matter is taken up. Five hundred and fifty pounds of resin are then added—a bucketful at a time, with more lie occasionally, until three hundred gallons of the strength above-mentioned have been used, keeping the blast in action the whole time, and the contents of the kettle as nearly boiling as possible. When the whole of the resin is melted, and thoroughly incorporated with the saponaceous mass, and the strength of the lies taken up, the blast should be stopped, and the contents of the boiler briskly boiled, and then allowed to rest, that the spent lies may separate and deposit. These being now drawn off, the soap is then brought to strength by fresh lies as in the ordinary process of soap-boiling. During the operation of the blast, the soap must be kept in an *open* or *grained* state; and for this purpose salt or brine is to be added when necessary. Experience has shown that it is better not to make a change of lie during the operation of the blast, when lie of the

strength above-mentioned is used; but if weaker lie is employed, one or more changes may be made. It is found desirable, also, that the soap should be kept in a *weak* state during the passage of the streams of air through the materials; otherwise it is apt to swell up, from the air hanging in the grain; and this is found troublesome to remove, requiring long boiling. If dark-colored materials are used, it is well to keep the blast in operation three or four hours after the resin is melted; provided the soapy mass is kept *weak* and *open* or *grained*.

Another improvement in the manufacture of soaps was invented by Mr. ANDERSON, by means of which the soaps are more completely purified. This is described by MORFIT as follows:—In the manufacture of yellow or resin soap, the ordinary process is that of boiling the materials upon successive portions of alkaline lie until they become *strength*; that is, until the oily matter is perfectly saponified, after which the curd so produced is subjected to a purifying operation termed *fitting*, performed as follows:—The lie used in boiling to strength is carefully pumped off from the soapy paste; and the latter is diluted with weak lie or water, and boiled to the proper consistence. After two days' repose the lies settle out of the perfect soap, and there is found below the latter an inferior or second quality of soap termed *nigre* or *nigger*. The perfect soap is cleansed or lifted off carefully from this, and transferred to the cooling frames; the mass of imperfect soap either being added to the next charge, or concocted into an inferior soap. The process followed in making curd soap, is to boil the materials upon successive lies until they become saponified; after which, and when the curd is of proper consistence, it is removed carefully to the cooling frames without further treatment. The invention of Mr. ANDERSON, it will be observed, does not interfere with the usual mode of producing the soap, but refers only to its purification, and begins at that point where the materials having been properly saponified, the soap *ribbons out* well on the finger. At this stage, instead of boiling out the head, and finishing as heretofore practised, the new process is commenced by pumping out or drawing off the strong lie on which the materials have been boiled, and then adding weak lie or water in successive portions, and boiling the whole until the mass assumes a proper appearance for fitting. The whole is now allowed to stand at rest for from twenty-four to forty-eight hours, or until the *nigger* or imperfect portion of the soap is deposited. This latter may then be separated, either by pumping it off from under the purified compound into an adjacent kettle, or by removing carefully the upper stratum of purified soap by means of ladles or buckets.

Whichever method be pursued, the cleansed material must now be treated with the proper finishing lie for curd soap; which being added, the whole is boiled until the soap becomes of sufficient consistence to be transferred to the cooling frames. When the materials employed in the production of this soap are very impure, the fitting or purifying process as above described is repeated one or more times; in which case after the first separation of the imperfect soap,

the remaining partially-purified material is treated with a lie only of moderate strength, instead of the ordinary finishing lie, and the whole is boiled with weak lie or water until sufficiently diluted to allow the proper performance of the fitting process; after which, time is allowed for deposition, the imperfect soap is again removed, and after the addition of the finishing lie, the remainder is boiled to a curd as before. The further treatment of the separated *nigger* or imperfect soap and its conversion into mottled soap, is effected by adding to it in an ordinary caldron the usual finishing lie for a mottled soap, and boiling until it is of proper consistence to be removed to the frames. The quantity obtained from one charge of soap by the fitting or purifying process, is not enough to be conveniently boiled by itself; it is therefore set aside, and six or more batches operated upon at one time.

SOFT SOAP.—This variety of soap differs in many essential particulars from those already described. The alkali used in its production is potassa exclusively, and the oil, either in whole or in part, a drying oil, as that of hemp seed, poppies, *et cetera*, or fish oil, as whale or seal oil. The theory of the reaction of potassa upon fats and oils is precisely the same as in the case of soda. Soaps with potassa base are, however, manufactured on an entirely different system to those of soda or hard soaps. In the latter, the soap is withdrawn from the lie when only a portion of the oil has been saponified, and fresh lies are added until saponification is complete.

In the production of potassa or soft soaps, no lies are separated during the whole course of operation; the only object being the combination of the potassa with the fat or oil. Potassa soap, therefore, of course contains the whole of the base of the oils or glycerin, which is expelled from combination by the stronger base, as well as the impurities always existing in the lie, as carbonate of and caustic potassa, chloride of potassium, sulphate of potassa, and in small quantities, many other salts, which in the manufacture of hard soaps are removed in the exhausted lies. Potassa soap, also, always contains a much greater proportion of water than hard soaps, the quantity being in the majority of instances from fifty to sixty per cent. If desired, the glycerin of the fat and saline impurities of the lie might easily be removed by the application of strong lies towards the completion of the process, but on the large scale such a system is never pursued. A much larger proportion of alkali is consumed by a given weight of oil or fat, when saponified by potassa, than when soda is used, one part of pure potassa being taken up by from four and a half to five parts of oil; and hence the quantity of real soap produced from a given weight of oil or fat when saponified by potassa is considerably greater than when the alkali used is soda; and this quantity is still further augmented by the large proportion of water, together with the glycerin and saline impurities always contained in the lies, and which, as above stated, are not removed from the soap. From the great analogy which exists between soda and potassa compounds, it would be expected that potassa soap would be separated from its solutions by chloride of potassium, as soda soap is by chloride of sodium. This, however, is not the case, as when to a solution of potassa soap, procured

by treating oils or fats with caustic potassa lies, a considerable quantity of chloride of potassium is added, no separation of soap takes place; the salt dissolves in the soapy mixture, and the solution remains clear. Potassa soap can only be separated from the lies and eliminated glycerin by adding strong potassa lies after the soap is complete, and the excess of alkali and the glycerin may then be allowed to subside, and subsequently be more completely removed by placing the soap to drain. On the large scale, however, as before observed, soft soap is never separated as above; the soap solution is boiled down until homogeneous and of a proper pasty consistence.

The process of manufacture of soft soap is as follows; the proportions of oil and lie being regulated according to the strength of the latter, and the qualities operated upon at once varying with the greater or less capacity of the boiling caldron. According to MORFITT, whose extensive experience in the soap manufacture renders his remarks of great value, the larger the caldron the better and more economical. To be properly proportional, the diameter should always be greater than their depth, and should be only half filled with material, as the soap when boiling swells up and rises considerably. In some soaperies the whole of the oil and tallow is introduced at once, together with a portion of the lie, and the remainder of the lie is added after some hours' ebullition; in others, both the oil and lie are introduced gradually. The lie should, indeed, always be gradually added, and in small quantities at a time, spreading it superficially over the whole mass. As soon as the two clear liquids, separately introduced, unite together, the whole becomes much thicker, and in some cases boils quietly, but in others swells up into froth. In the latter case it must be thrashed with a stirring pole, and dosed with a sufficient quantity of lie to lessen the commotion and prevent loss of the material by running over. The caldron requires to be constantly watched while over the fire. If too much lie is added at the commencement, no union is effected between the oil and the alkali; and if the lies are too strong they seize on the oil too rapidly, and instead of becoming thick and viscid, the mass becomes clotted. This latter inconvenience may be remedied by adding lies of a lower degree of strength. If the lies are not sufficiently strong, combination ensues so tardily that part of the superabundant water must first be expelled by evaporation before a perfect union between the oil and alkali can be effected. When combination is perfect and the great foamings have subsided, the pasty mass should become clear and transparent, and free from clots or granules, and no acrid taste should be perceptible. To ascertain if this be the case, a small sample is taken out and cooled. If it should not be of proper consistence and free from opacity, the boiling is continued, and after some time another sample is taken, and so on until the soap is properly finished. If the test sample thickens on cooling, has a brown color, is perfectly homogeneous, and is not ropy when worked between the fingers, the soap is finished, and the fire should at once be withdrawn. A fair criterion of the quality of the soap is said to be furnished by a peculiar phenomenon observable during its cooling; a little opaque zone forming around the test-portion taken

from the caldron for an assay, indicates perfect saponification, and is called *strength*, the absence of which denotes a deficiency in strength; and when the zone vanishes soon after having made its appearance, the soap is said to have *false strength*. When it comes in the best form the soap is perfect, and may be secured in that state by removing the fire, and then proceeding as subsequently directed.

To allay the foaming and render the finished soap fit to be transferred to the barrels or casks without endangering its detergent quality or diminishing its causticity, the soap should be cooled as rapidly as possible. For this purpose a quantity of ready-made soap—a ton or more, according to the size of the caldron—is added to the hot mass. This, in melting, rapidly abstracts a portion of the heat of the recently made soap, until the degree of that and its own is uniform. The foaming having subsided, the soap is raked off into the barrels, in which it is sent away. In the manufacture of soft soap MORET observes, that it is better that the boiling should be too much than too little protracted. Soap which is not sufficiently cooked, changes and spoils, while the only disadvantage produced by excessive boiling is a diminution in the quantity of the product. The usual time requisite for a charge is six or seven hours, but varies with the strength of the lie, the temperature of the atmosphere, and other incidental circumstances.

In Great Britain a small proportion of tallow is usually introduced as one of the materials for the production of soft soap. This addition is for the purpose of producing the solid white granulations of stearate of potassa termed *figging*, because the soap then resembles the granular texture of a fig. Hence British soft soap presents the appearance of a brownish transparent body, through which white grains are disseminated. These figged granulations do not usually make their appearance until two or three weeks after the soap has been made, and during the hot summer months they do not appear at all. They are improperly considered to be a proof of the good quality of the soap, and hence the figged appearance has been imitated by the admixture of starch. Messrs. LUND and UNSWORTH of Liverpool are said to be the largest makers of soft soap in England. They generally turn out fifty or sixty tons weekly of a most excellent article.

The Scotch process for manufacturing soft soap is as follows:—Two hundred and seventy three gallons of whale or cod oil, and four hundred pounds of tallow are introduced into the soap pan, together with two hundred and fifty gallons of potassa lie, of such strength that one gallon contains six thousand six hundred grains of real potassa. Heat is now applied to the pan, and as the mixture approaches the boiling temperature, much froth appears, and to prevent boiling over, it is beaten down on the surface. Should it subside quickly into a doughy looking paste, it is an indication that a too strong lie has been used. Its proper appearance is that of a thin glue. There should now be added about forty-two gallons of a stronger lie, equivalent to eight thousand seven hundred grains of potassa per gallon, and after a short interval, an additional forty-two gallons; and thus successively

until nearly a total of six hundred gallons has been introduced. After properly boiling, to complete the saponification of the fats, soap will be obtained amounting in quantity to six thousand four hundred pounds, from the above proportions of materials.

American soft soap, MORET states, differs very little from the preceding in its mode of manufacture; two hundred pounds of oil saponified by seventy-two pounds of potassa in lies of specific gravity 1.110 = 22° Twaddell, yielding four hundred and fifty pounds of finished soap. Fish-oil soft soap has usually a dark-brown color, and that made from refuse fat and oil, a dirty-white shade. Soap made with colza oil is slightly bluish. When hempseed oil is used, the soap has a greenish color. The latter is by some consumers preferred to other kinds of soft soap; and hence ordinary soft soap made from fish oil is frequently tinged green by adding a small proportion of powdered indigo, or a solution of indigo in alkali, the yellow of the soap forming a green with the blue of the indigo. Soft soap is always of a pasty consistence, and even if excessively boiled, does not harden, but becomes scorched and dry. In this country it is chiefly used for fulling, and for the scouring and cleansing of woollen stuffs. Being possessed of greater solubility, and having a much more powerfully detergent action, it is also especially applicable for scouring floors and wooden utensils. In Germany, Belgium, and Holland, it is also used for washing linen, which thereby acquires a most disagreeable odor of oil. When chloride of sodium is added to soft or potassa soap, decomposition ensues, the chlorine of the salt seizes the potassium of the soap producing chloride of potassium; and at the same time, the sodium takes the place of the potassium in the soap, and a hard or soda soap results. The proportions recommended by PELLETIER and others for the conversion of soft into hard soaps, by means of the above-mentioned decomposition, are six pounds of salt to every three pounds of oil, and the solution of the salt in water is to be added in small portions and gradually to the soap, the latter being in a state of ebullition. The soda soap produced separates quickly from the lie, and the operation is terminated in the usual way. This process for producing hard soap is of great importance in those countries where soda is not to be procured, as potassa and its salts may be substituted for the latter in the process of saponification.

SILICATED SOAPS.—Many varieties of soap are met with in commerce termed silicated soaps. They are produced either by the addition of silica itself or an alkaline silicate to the soap paste, just before cooling and solidification. Under this title are included also those soaps admixed with pipe-clay, and matters of a similar nature, which, though not strictly silica soaps, are usually classed with them. Sand soaps differ from silica soaps inasmuch as in the latter the admixture has been prepared artificially, while in the former common white sand is the silicious ingredient, and the only preparation it has undergone is finely sifting. In the preparation of sand soap, the finely-sifted sand is added to ordinary white soap and thoroughly incorporated with it while in the pasty condition, in the proportion of seven or eight per cent; and as soon as the mass has

cooled, it is taken from the frame and cut into tablets or moulded into balls. Of the three silicated soaps, the first that claims mention is that prepared by Mr. GOSSAGE's patent process. It consists in the introduction into soaps prepared from fatty or resinous materials of a highly concentrated solution of silicate of alkali. The process for the preparation of this silicate, termed also *soluble glass*, is described in the specification as follows:—When soda is used as the alkaline solution to be combined with silica, nine parts of soda ash are mixed with eleven parts of clear sand, and the mixture is to be fused in a reverberatory furnace, provided with a tap-hole through which to allow the finished product to run off. Sufficient heat is to be applied to the mixture, stirring from time to time until combination has been effected; the product is then drawn, and received either in metallic moulds, or in moulds formed of damp or moistened sand. The charge for a furnace having a bed or sole measuring sixty square feet, is about a ton of the mixed sand and alkali, and each charge requires four or five hours to be properly fused and combined. For the preparation of silicate of potassa the proportions are equal weights of crude carbonate of potassa and sand, and these are melted exactly as in the production of silicate of soda. It is always desirable to use such proportions of alkali and sand for the production of the silicate, that the latter may be almost wholly soluble in water; when the alkali is deficient, however, this is not the case, and to obtain perfect solution, it is necessary to use as the solvent a solution of caustic soda or potassa.

The solution of the perfect silicate may be effected simply by grinding the latter to powder, and agitating this in a pan containing boiling water; but a much preferable method of solving is, by the employment of an apparatus consisting of a vessel formed of iron plates, or other suitable materials, which vessel is fitted with a perforated diaphragm or false bottom placed about mid-way between top and bottom. The silicate, first broken into small lumps, is placed upon the false bottom, and hot water is introduced into the vessel to a sufficient height to cover the pieces of glass to be dissolved. Steam is then introduced into the water so as to maintain the latter at a high temperature.

As the glass dissolves, it communicates additional gravity to the water, and the heavier solution descends in the vessel whilst the lighter fluid rises, and coming in contact with the glass also dissolves it, and acquiring density again descends. In this manner a continued circulation of the fluid takes place, and the glass becomes nearly all dissolved, yielding a strong solution.

After allowing undissolved matters to deposit, the solution is transferred to a cast-iron evaporating pan, and by the application of heat concentrated until of specific gravity 1.450, when it becomes viscous on cooling, and is then in a condition to be added to the soap. When the solution of the silica is to be added to a soda soap, the latter, prepared in the usual manner, is to be transferred from the caldron into a tub or pan, termed the mixing vessel, capable of containing about fourteen hundredweight of soap, and the viscous solution of silicate of soda is to be added in such proportions as to yield the particular quality of soap

desired to be produced; and the mixture is then well agitated by means of crutches or paddles. The soap and the viscous solution should be each at such a degree of heat that the mixture, when formed, may be at a temperature of 160°, and the agitation is to be continued until the temperature is reduced ten degrees, that is, to about 150°. The mixture is then transferred to the cooling frames, and agitated therein by means of crutches, until it becomes of such consistence as to render its continuance no longer practicable.

Although the mixture of the solution of silica with the soap may be effected by means of crutches worked by hand, as above described, it may be stated that when a more rapid agitation is applied than can be effected by this means, the soap produced is a more perfect mixture, and of more uniform quality.

For admixture with soft soap, the soluble glass is formed by the fusion of a mixture of sand and potassa, as previously mentioned, for the preparation of a silicate of potassa. This is dissolved, and after concentrating the solution to the viscous condition, it is mixed with the soft soap, exactly as described in the case of soda or hard soaps. As the proportional amount of alkali contained in a mixture of soap with soluble glass is greater than that contained in the unmixed soap—if it is desired to reduce this amount, as the excess of alkali may be injurious for some purposes to which the soap may be applied, it is effected by the addition to the solution of the silicate of sulphuric or hydrochloric acid, previously to its reduction to the viscous condition. The mixed silicated soaps may be obtained of any requisite degree of hardness by the greater or less concentration of the solution of soluble glass. The compound soaps produced by the above process, the patentee states, are possessed of valuable detergent properties, independently of the real soap contained in them.

In the process invented by Mr. SHERIDAN for the preparation of silicated soap, either calcined flint, or quartz, or sand is used for the production of soluble glass. If sand is the silicious ingredient, he directs that it be mixed with carbonate of soda in the proportion of one part of sand to three of soda, and the mixture is then to be calcined to fusion in a reverberatory furnace. The product of calcination is drawn out into water and dissolved by the aid of heat. Thus far the process resembles that of Mr. GOSSAGE. Mr. SHERIDAN, however, now directs that a current of carbonic acid be passed through the solution of silicate of soda, whereby the silica is displaced from combination and precipitated in a gelatinous form. From this the liquid containing the soda, reconverted to the state of carbonate, is withdrawn, and evaporated to dryness for use again; the precipitated silica is mixed with caustic soda or potassa of specific gravity 1.1515 = 30° Twaddell, and boiled for eight hours, with constant stirring, until it becomes a homogeneous mass. This latter part of the process seems a very useless operation. It is simply the destruction of a compound already in the liquid condition, and its reproduction in exactly the same state, but by another and more objectionable mode of treatment—objectionable because combination between silica and an alkali is effected

much more easily and perfectly by fusion than by ebullition of the materials together with water. When the silicious ingredient is flint or quartz, the calcined material is to be reduced to nearly an impalpable powder by wet grinding with horizontal stones. The powder obtained is thinned out with about twenty per cent. of water, and then boiled with caustic soda lies of the strength above mentioned, for eight hours, or until it becomes a homogeneous mass. In this condition, in which it is technically termed *detergent mixture*, it is ready to be mixed with the soap paste.

A method for the preparation of silicated soap was also invented by Mr. DUNN, in which either silica itself, or an alkaline silicate, is made to unite with soap under steam pressure. According to the author of this process, the method is also applicable to the manufacture of soap even when silica is not an ingredient, with the advantage over the usual mode of boiling, of effecting a more perfect union of the ingredients in a shorter time, with greater economy, and at a diminution of expense.

The apparatus employed is represented in section, Fig. 506. The boiler, B, should be furnished with a

Fig. 506.

man-hole, safety valve, a thermometer plunged into a mercury chamber, and all the ordinary appendages of such an apparatus. A is the feed-pipe, and C the pipe through which to discharge the finished product. The crushed flint or quartz to be combined with the soap is mixed with caustic soda or potassa lie, in the proportion of one hundredweight of silica to one hundred gallons of lie of specific gravity $1.16 = 32^\circ$ Twaddell, and introduced into the steam-tight boiler. The fire is then kindled, the valve being so regulated as to allow the temperature of the materials to rise gradually to about 310° , or at a pressure of fifty to seventy pounds to the square inch. When it has remained at this temperature for about three or four hours, the contents are discharged and cooled down. The solution of silicate of potassa or soda thus obtained, according to the kind of alkali used, is added in the proper proportion to the soap paste, either in the caldron or frame after the saponification is complete, and before the soap is become cold.

SULPHATED SOAP.—The variety known to manufacturers and in commerce as sulphated soap, is produced by a process patented by Dr. NORMANDY. The object of the patent appears to be, to enable manufacturers to produce a soap from inferior oils and fats possessed of detergent properties, and also of a hardness equal to that from oleaginous bodies of much higher value. The great objection to soaps made from the inferior kind of fats, and also to soaps containing more than a due proportion of resin, is their very ready solubility in water, in consequence of which great waste is always experienced when these soaps are used for washing or cleansing purposes. By Dr. NORMANDY'S process, a soap is obtained from the cheaper oil possessed of equal detergent properties, and also of an equal degree of hardness, to that obtained by the employment of the more valuable fats and oils; thus rendering a large class of oleaginous bodies available in soap-making, to which purpose they were not previously applicable. The following, extracted from the specification of the patent, will render the process sufficiently intelligible.

When the soap is made in the usual manner, and is ready to be cleansed, there is to be introduced and crutched into it a certain quantity of neutral anhydrous sulphate of soda, or of neutral sulphite of soda, or of the two salts conjointly. These salts have the property of imparting to soap made with more than the usual proportion of resin, or with those kinds of fat or grease known as *weak goods*, a greater degree of hardness than they would otherwise possess; and of rendering such soaps generally of a paler color, and enabling them to retain their weight better than would be the case without such addition. The soap containing sulphite of soda has, in addition, the property of removing from textile fabrics and fibrous substances the chlorine which they are apt to retain after bleaching. The mode of procedure with the sulphate of soda, or *salt cake*, is as follows:—

The salt is to be treated with a quantity of hot water, less than is necessary to dissolve the whole of it, and to the saturated solution thus obtained as much solution of caustic or carbonate of alkali is added as is necessary to impart to the liquid a faint alkaline reaction. This addition is made not only to saturate any free acids that may be present, but also to remove the sesquioxide of iron always contained in crude salt cake, and which, by this treatment, will be precipitated. When this precipitate has completely subsided, and the supernatant liquor is perfectly clear, as much of the latter is added to the soap paste as is necessary to confer upon it the requisite degree of hardness when cold; the particular quantity varying according to the nature of the fat or oil saponified, or to the proportion of resin present. The mixture of salt-cake solution and of soap are to be thoroughly incorporated by stirring or crutching, continuing the agitation until the mass has become so hard that the stirring can be no longer practised. When the sulphite of soda is used, the patentee recommends that it be dissolved in as little hot water as is necessary for the purpose; and the solution is added to the soap exactly as above described for the sulphate of the same base, or salt

cake. If the salt be a bisulphite of soda, or if it is not in a state of purity—in other words, if it contain an excess of sulphurous acid, or be contaminated by oxide of iron—the excess of acid should be neutralized, by adding to the solution of the salt as much carbonate of or caustic soda as will impart a slight alkaline reaction; and after allowing the separated matters to deposit, the clear supernatant liquor is to be introduced and crutched into the soap, precisely as directed above in reference to the salt cake. The usefulness of this invention has been tested and carefully examined by several eminent chemists, among others by HOFMANN, MILLER, and URE, all of whom speak in high terms of its merits; and the Editor is gratified to have this opportunity to add his testimony as to the value of an invention the object of which is to supply a cheap soap as economical to the consumer as that produced by the more expensive fats and oils.

SNELL'S DEXTRIN SOAP.—This soap contains, in a state of admixture, a greater or less amount of vegetal matter, obtained from either potatoes or other sources. It is termed by the inventor dextrin soap; as prepared, however, according to his directions, no dextrin enters into its constitution, but, instead of this, woody fibre and unaltered starch. The method of preparation is said to be preferable to the old plan of combining farina with alum and soda in the manufacture of soap, inasmuch as it insures the perfect incorporation of the admixture with the saponified fats and oils, whereas, when they are previously acted upon by alum and soda, their tendency to union is partially impaired. The vegetal matter used by the inventor is obtained from potatoes as follows:—The washed potatoes are reduced to as fine a pulp as possible, by a revolving cylinder furnished with parallel plates of steel or iron. These plates have fine teeth like saws, the teeth rising just above the surface of the cylinder under a hopper, which receives the potatoes. The pulp falls on sieves or screws below, and passes over the upper sieve. This is a plane of five feet in breadth and eight in length, with one or two bars crosswise, covered with a wire-cloth of thirty holes to the inch. At the top, and about midway down the sieve, are pipes containing water, so arranged that the water shall run from the pipes through small holes the whole breadth of the sieve, the finer parts of the potatoes running through the meshes of the sieve into a vat. The finer parts, termed dextrin by the inventor, which fall on a wooden plane placed under the second sieve, but in a contrary direction thereto, are received in vats, where they are repeatedly washed over sieves of finer wire-cloth until cleansed from all impurities. The grosser parts—fibre—are washed over coarse sieves. The finer parts, having precipitated, are taken up in buckets, and are fit for use; the coarse portion remains in a vat covered with water until required for use, or the dextrin may be dried by any convenient means, and preserved in the dry state. The usual proportion of dextrin to soap is from three hundred to three hundred and fifty pounds of the first, mixed with a hundred and fifty pounds of water, to every ton of tallow or oil saponified. The mixture of water and dextrin having been allowed to stand for an hour,

should be further treated with six hundred pounds of water, as subsequently described. The white soap should be made of tallow, and by steam heat; and when as much alkali has been added as can be taken up in the usual way, and when the soap is in a fit state to transfer to the frames, there is to be added from four hundred and fifty to five hundred pounds of dextrin in its wet state; and after being further mixed with six hundred pounds of boiling water, or as much as is sufficient to convert it into a thick paste, this paste is to be poured in by pailfuls into the soap, the latter being well agitated during and after each addition. When the mixture is homogeneous, and has been heated, it may be put into a frame for cooling, and afterwards cut up in the usual way. Before adding the mixture of dextrin and water, the spent lie must be pumped or otherwise withdrawn from the caldron. When, as in the ordinary method of manufacture, yellow soap is made from resin, and is *fitted* or purified from portions of imperfect soap, coloring matters, *et cetera*, it should be heated with steam, and dosed with the proper proportion of dextrin, as above directed. If no resin is used, a larger quantity of dextrin may be applied, and the operation of fitting is not then absolutely necessary. In the manufacture of either the brown or yellow variety of common soap, the addition of a quantity of the fibre, first mixed with a sufficient quantity of water to make it of thick creamy consistence, will render the product, especially when an excess of alkali is present, of much better quality and color, and it will then also dissolve much less rapidly in hot water. If a naked fire is used for the soap thus mixed, the dextrin is liable to become carbonized, and the separated charcoal would then communicate to the soap a black, or at least a darker color, than when steam is applied. The latter should therefore be always used in the above process of admixture.

A person named HAWES some years ago invented a process for the production of soap, in which intimate combination and admixture of the soap ingredients without boiling induces combination and perfect saponification of the fat with the alkali. By this method, the high degree of heat requisite in making soap by the usual process is entirely dispensed with. His mode of procedure is, as follows, described as for tallow; but, according to the inventor, it is equally applicable to the oils and fatty matters ordinarily employed as soap ingredients:—Two tons and a half of tallow, or any given quantity, are taken and melted at as low a degree of heat as possible, and then mixed with the quantity of alkaline lie required to completely saturate the tallow and convert it into soap. The mixing is performed by mechanical means. Ordinary soap boilers' lie is used, preference being given to that made from the strongest and purest alkali. The saponification of the tallow or other fatty matter, may be ascertained by its absorption or combination with the lie, care having been taken, in the first instance, to use a sufficient quantity of the latter; the proper proportion, it must be observed, varying according to the nature of the fat or oil. To each hundred pounds of tallow are required about

twenty gallons of lie, made from strong alkali, and of specific gravity $1.125 = 25^{\circ}$ Twaddell. An ordinary boiling caldron may be used as the combining vessel, with the addition of a machine to produce an intimate admixture, and the minute redivision of the tallow. Figs. 507 and 508 will convey an idea of this apparatus.

Fig. 507.

An upright shaft, A, Fig. 507, which may be of wood or iron, and from which arms, a, a, a, a, radiate to the sides of the caldron, is fixed permanently or temporarily in the copper. The mode of fixing and the material used, will depend on the nature of the caldron and the convenience of the manufacturer. An oscillating or rotatory motion is given to the shaft and connected arms by any of the ordinary methods of communicating motive power. If more convenient, a cylinder—Fig. 508—may be employed, with a shaft, C, passing through it horizontally,

Fig. 508.

and from which arms, c, c, c, c, c, radiate, when a rotatory motion will thoroughly incorporate the fatty matter and the lie. For two and a half tons of tallow the cylinder should be about six feet in diameter and twelve feet in length. At D it must be provided with convenient doors for filling and discharging the materials. The caldron or cylinder having been charged with tallow, motion is communicated to the machine, and the lie is then gradually added. In a short time every particle of the fatty matter will be brought into contact with alkaline lie, and by such means saponification will be effected. The agitation must be continued for about three hours, or until the tallow appears to be completely saponified, which is known by the mass becoming thick, after which it is allowed to stand from one to four days, according to the quantity of the paste. When a cylinder is used in the above operation, the lie is run in, and motion communicated to the shaft immediately after the introduction of the tallow, the latter being only sufficiently heated to retain it in the fluid state, and the agitation is continued from three to four hours, or less if the tallow is perfectly saponified before its expiration. As the benefit of this process arises mainly from the saponification of the ordinary materials in a comparatively cold state, it is desirable that as soon as the mass thickens and the lie is absorbed, the cylinder should be emptied and the contents turned into an ordinary caldron, preparatory to being finished and converted into yellow soap by the addition of resin, or into mottled or white soap by the operation of finishing lies, according to the usual method. By this transfer from the cylinder to the caldron, time is allowed for the combination of the tallow and alkali to become perfect.

Another method for the manufacture of soap, according to the patentee more particularly applicable to palm-oil soap, was devised by Mr. WALTERSON of Manchester. The inventor claims for his process that a purer and more perfect soap is produced in a much shorter period of time than by the ordinary method, the soap being sufficiently hard for sale or use in the course of a few hours. His method consists in a mode of mixing or combining the oils or fatty matters employed with caustic soda, and in subsequently adding water for the purpose of converting such mixture or produce into soap. The ingredients used are animal or vegetal oil, either separately or mixed, caustic soda lie of 22° Twaddell, and water if possible free from any earthy or metallic impurity. The following description of the process applies more particularly to the production of palm-oil soap, and requires to be variably modified when other oils or fats are to be saponified. The quantity of bleached palm oil taken for one operation is seven hundred and eighty-four pounds; and after having melted this in a caldron, there is to be added gradually four hundred and seven pounds of caustic soda lie, testing 22° Twaddell, and the whole is carefully and thoroughly intermixed by agitation. The heat is then gradually increased, and the mixture constantly stirred, so as not to allow it to concrete on the bottom of the pan. After the operation has been continued three or four hours, the mixture assumes a whitish appearance, and by continuing the heat the aqueous portion is entirely evaporated, and the mass reduced to a perfectly dry state. The heat is now increased, and in a short time the mass again assumes the liquid form, and becomes of a brown color, which, according to the inventor, shows that combination with the alkali has been effected. The fire is then speedily withdrawn, and the agitation of the mass is continued as long as any fear of scorching is apprehended, after which the pan is left to become cool. The solid product of this operation is then to be broken up into powder, to which is afterwards added forty-five gallons of water, and the mixture is well agitated for about half an hour. Heat is then applied, and the contents of the pan raised to boiling, and kept so for about three hours, the stirring and agitation being continued during the whole period. As soon as the evaporation has been carried to the desired extent, and the soap appears of proper consistence, it is allowed slowly to cool. The contents of the pan, still in a liquid form, are then transferred to the ordinary frames, and left to cool and solidify, and in twenty-four hours the soap will be sufficiently hard to cut into bars. Soap prepared according to the above method, is never of so fine a color as that prepared by the old process from the same ingredients; besides which it is also less pure, as it contains of course all the saline impurities of the lie. The only advantage appears to be that the soap is finished in a much shorter period, but this, in the Editor's opinion, does not counterbalance the great disadvantages above mentioned.

Since the remission of the duty on soap, a process for its manufacture has been introduced by H. C. JENNINGS, but has not been adopted on a very considerable scale; for though it undoubtedly gives a purer

and more perfect soap, the expense of production is much greater. In this method the oleaginous ingredient used is stearic or margaric acid as nearly pure as possible, and the alkali is derived from bicarbonates of potassa or soda; the fatty acids, possessing a decomposing power over these salts, render their previous caustization unnecessary. The fatty acids and solution of alkaline bicarbonate of specific gravity 1.500 are mixed in proper proportions, and heated at 212° until an intimate combination is obtained. The mass is then allowed to cool down to about 60°, and there is now added to each hundred pounds one pound of solution of ammonia of specific gravity .880, and the same quantity of the strongest caustic potassa lie. These are to be added gradually, and well stirred with the soap until thoroughly mixed. The quantity of caustic alkali required to be added is greater or less in proportion to the state of purity of the fatty acids saponified. Lastly, the separation of the soap is effected in the usual manner by means of common salt or sulphate of soda. In the manufacture of yellow soap by the preceding method, there is added previously to the addition of caustic soda or potassa lie, fifteen to eighteen pounds per cent. of resin, first dissolved by boiling with a solution of pearl ash and common soda ash in equal proportions, so as to give a solution of specific gravity 1.800, while boiling hot. This is added to the solution of soap, and afterwards there is poured in a sufficient quantity of caustic lie to produce perfect saponification, and the soap is then separated as before. The Editor would especially recommend the above process of saponification for the production of the potassa soap ordered by the London Pharmacopœia. It is indeed the only method by which a perfectly pure potassa soap can be procured. This soap not being separable from its solutions, like soda soap, by salts of soda or potassa, as ordinarily prepared, is always contaminated by glycerin and other impurities.

In the manufacture of the variety known as GWYN and WILSON'S soap, the oils and fatty matters employed are heated with concentrated sulphuric acid, by which decomposition of the fats is effected, and glycerin eliminated, while the oily acids probably enter into combination with sulphuric acid. The fat so treated becomes much harder and less readily fusible, and is likewise rendered much more easily saponifiable, although it is true that not only a greater proportion of alkali is required, but the amount of product obtained is less than when the fat is saponified in the usual way. The following is the method of procedure as described by the inventors:—Ten tons of palm oil, whale oil, or other oily matter, are put into a wrought-iron vessel provided with a perforated steam worm, through which steam is admitted until the contents are heated to 350°. The fatty matter is then run into a tank formed of brick, lined with lead, and sunk into the ground. The tank is furnished with a pipe for the introduction of steam, but which does not terminate in a worm, as it would be liable to become choked by the sediment from the fat. The cover of the tank is made of wood, lined with sheet lead, and has two man-holes closed by an oil joint about eight inches deep;

through the cover a pipe passes connected with a high shaft, to allow the escape of offensive vapors. Two thousand pounds of concentrated sulphuric acid, specific gravity 1.80, are poured into the tank, the temperature of the mass being at the same time carefully watched by means of a thermometer immersed in it, and not allowed to exceed 350°. The heat is regulated partly by slackening the speed at which the acid is poured in, and partly by diminishing the quantity of steam admitted into the tank. The introduction of steam is continued throughout the operation; but as soon as the whole of the acid has been added, the fire employed for heating the steam is extinguished, and after that the steam continued for about four hours. The steam is heated after it leaves the boiler, by passing through pipes placed over a fire. At the expiration of four hours the steam is shut off, and a large pump introduced through a pipe in the cover of the tank; then as soon as vapors cease to be evolved, and the pump can be worked, the product is pumped into a wooden vessel, lined with lead, and provided with a steam worm. In this vessel the fatty matter is washed by means of free steam, with about half its bulk of water, for two hours, and then allowed twelve hours to separate.

TOILET SOAPS — SCENTED SOAPS.—The great variety of soaps thus designated, are usually prepared by remelting and clarifying white or curd soap, and adding various perfumes, colors, *et cetera*. These operations belong more properly to perfumery than to the soap manufacture; and their preparation has therefore been included in the article devoted to the consideration of this art, Vol. II., pages 676 to 679. Sometimes, however, since the remission of the soap duty in this country, the perfumer prepares soap directly by the cold process above described, and this is a more convenient method. The marbling of these soaps is produced by rubbing up the coloring material, such as vermilion, smalts, or ultramarine, with a little olive oil or soap, a small portion of which being taken on a palette knife, is pushed through the melted mass; thus the pink color of rose soap is produced by vermilion; blue by means of ultramarine; and brown by the addition of the various kinds of ochres and umbers. The cakes or tablets are formed by placing a soft mass of soap in a mould fixed in a lever press; the mould consists of a top and bottom die, fitting into a loose ring; by a sudden pressure the shapeless mass assumes the form of the ring, and is embossed on the top and bottom. Soap is ornamented with colored cameos by first forming the cake at a press, which makes a depression for the reception of the differently-colored soap, which latter is put in by hand, and the colored portion is embossed at a second press.

A very superior and beautiful marbled soap is manufactured by the Messrs. CROSFIELD of Warrington, Lancashire.

NAPLES SOAP.—This, so highly esteemed as a shaving soap, is said to be produced by saponifying mutton suet with lime, and then separating the fatty acids from the soap so formed by means of a mineral acid. These fatty acids are afterwards combined with caustic potassa by ebullition in the usual way. FAISZT, who

examined Naples soap, gives the following as its composition centesimally :—

Fatty acids,	57.14
Potassa combined with fatty acids,	10.39
Sulphate of potassa, chloride of potassium, with a trace of carbonate of potassa,	4.22
Silica, <i>et cetera</i> ,	0.46
Water,	27.68
Loss,	0.11
	100.00

ADULTERATION.—In the manufacture of soap certain substances are frequently added besides the fat, alkali, and water essential to its production. These additions cannot always be considered as sophistications, inasmuch as in some cases the quality of the soap is thereby greatly improved. Thus, in Dr. NORMANDY'S patented process, the addition of a small proportion of fused sulphate of soda to an otherwise very soft soap, confers upon it a hardness which prevents its melting or dissolving too rapidly in the process of washing. Though it may be said that the manufacturer is, by such addition, enabled to use an inferior oil or fat, still no deception is practised, as the soap so produced is little inferior in detergent properties to the soaps of the better kinds of fat, while it may be purchased at a much lower price. Other additions are also frequently made. In those cases, however, in which the substance added rather improves than deteriorates the quality of the soap, it cannot be considered as a fraud. It is true that soap is extensively and fraudulently adulterated in the true sense of the term. The Editor would remark, however, that in his opinion the public craving for cheap goods has urged upon the makers the necessity of preparing soap at a low price; and as the simplest mode of doing so was to incorporate saline water with the curd, when in the act of solidifying in the frames, to the extent commensurate with the reduced price, this mode has been adopted. So far as this addition is concerned, it does not involve the character of the manufacturer or dealer; but when the addition of water is covertly made by the maker, and the article sold as a better quality, as is frequently done, at once the public is defrauded. In like manner, dealers are in the habit of purchasing soaps at cheap rates—soaps which are highly adulterated—with the view of disposing of them at prices which better qualities command. Here, again, the consumer bears the weight of the villany, whilst its guilt presses upon the dealer, and the maker even does not escape with impunity. Certainly the maker, and the maker only, can protect the public from fraud in the matter of soap. By making certain qualities of soaps with definite and invariable amounts of ingredients, the public would in a short time become so well acquainted with the quality of the article, that inferior kinds which the cupidity of some makers might induce them to utter, would rapidly meet with its condemnation. If, however, the consumers will always purchase in the cheapest market, and whatever be the price asked, will, if possible, obtain the article at a still lower rate, they must expect to be imposed upon.

ANALYSIS.—Under this head the most important point to be considered is the proper amount of water in soaps. The proportion of water in mottled or mar-

bled soap, should never exceed thirty to thirty-five per cent. It is indeed impossible to introduce an excess of water into the paste of mottled soap, since the mottling being due to the presence of sulphide of iron and other ferruginous compounds, held partly in solution and partly in a state of suspension, if the soap has not a certain retentiveness the insoluble iron compounds would precipitate, leaving the soap perfectly white. The admixture of water with mottled soap is, however, practised in another way, namely, by plunging the soap as taken from the frames into a solution of salt, when it may be made to absorb from eighty to eighty-five per cent. of water, and become so soft as to be kneaded easily between the fingers. Properly prepared white soap should contain from forty to forty-five per cent. of water. Frequently, however, the proportion amounts to fifty-five or sixty per cent., and cases have been known in which soaps, combined with from eighty-three to one hundred and fifty-four per cent. of water, have been sold. This is either added directly to the soap when run into the frames, or the soap is kept for some time in a solution of salt. The proportion of water is also sometimes increased by submitting the bars of soap to the action of high-pressure steam in tight chests or bins; also by boiling the soap in high-pressure coppers before *cleansing*.

The proportion of water contained in a sample of soap, may be most readily ascertained by treating a portion in a water or oil bath, until it ceases to lose in weight. Two ounces or more of the sample to be examined should be taken and reduced to small thin shavings. Of these, after carefully mixing together, one hundred grains are taken, placed in a small porcelain or platinum crucible, and dried by exposure in a water bath for a sufficient length of time. When the water is completely disengaged, that is, when after repeated trials the weight remains constant, the operation is at an end. The difference between the first and last weighing indicates the per centage of water present. As previously mentioned, marbled soap should not contain more than thirty to thirty-five; and white or yellow forty to forty-five per cent. of water. The amount of water contained in soap may also be estimated indirectly as follows:—From five hundred to a thousand grains of the sample are taken and dissolved in water. To the solution hydrochloric acid is added in excess. Decomposition of the soap ensues, the greasy matters rise to the surface, and must be collected on a weighed filter, and when well washed and dried, carefully weighed, deducting the counterpoise of the filter. The filtrate, together with the washings, is now evaporated to dryness, and, after carefully drying, the weight of the residue is taken. This latter contains the alkali in the form of chloride, every one hundred parts of which indicate fifty-three parts of soda, or sixty-three of potassa soap, according as the soap under examination is a hard or a soda soap, or a soft or potassa soap. The amount of greasy matter or alkali thus ascertained is subtracted from that of the soap taken, and the remainder expresses the proportion of water present. Mottled soap treated as above should yield of fatty acids sixty-four parts, of soda six parts, and thirty parts of water. White soap should give of

fatty acids fifty parts, of soda four and a half parts, and of water forty-five and a half parts.

It is evident that if other substances are present than those indicated, the results obtained by the foregoing method will be to that extent inaccurate. In such cases the other method must be pursued, and if it is desired to estimate also the proportion of fatty acids and of alkali, special examinations must be made as will be explained presently. Whenever the object is solely the determination of the amount of water, the method by direct evaporation is the simplest and best. To ascertain the proportion of oil or fat in a given sample of soap, the following process is recommended by DUMAS:—

One hundred grains of the soap are taken and dissolved in four or five ounces of boiling water, and the solution is filtered. A sufficient quantity of dilute acid is added to effect neutralization, and afterwards a weighed portion of pure and dry white wax. The whole is then heated until the wax is liquefied, and has combined with or taken up the oil or fat liberated from the soap by the stronger acids. After allowing it to cool the cake of wax obtained is removed and weighed; the increase above the original weight of the wax indicates the proportion of fat, oil, or grease contained in the soap. If the fatty matter of the soap when liberated by the acid itself concretes on cooling, the addition of wax is unnecessary, as the fat may be weighed *per se*. The liquid decanted from the fat, or solidified wax, may afterwards be submitted to examination, to ascertain the nature and state of purity of the base. If this is intended, hydrochloric acid should be used for the liberation of the fat, and then the presence of potassa is immediately recognized by the production of the very characteristic yellow precipitate, on the addition of bichloride of platinum. To ascertain the nature of the fatty material, DUMAS directs the aqueous solution of the soap to be saturated with tartaric acid, the fatty acids to be collected, and their point of fusion carefully observed. It is a matter of great difficulty to determine the particular kind of fat or oil used in the production of the soap under examination; yet by the above method, it is possible at least to prove the identity of the fatty component; as, for instance, whether the soap is made from tallow or from oil, or whether it is of the same kind as the sample from which it may have been purchased. The odor evolved by the fatty acids at the moment of decomposition of the soap by a stronger acid, or that developed when the fatty matter so liberated is treated in a small porcelain dish, will often indicate the nature of the fatty substance employed in its production, or that at least which is present in the greatest proportion. According to NORMANDY, another test as to the quality of the soap is, that the fatty or oily acid should be readily and completely dissolved by hot alcohol. The estimation of the proportion of alkali contained in a sample of soap, is frequently a point of great difficulty. When only one alkali is present, the determination is most easily effected by means of a test acid, and the operation is performed exactly as directed in the estimation of the value of potassa, Vol. II., page 729. For hard or soda soaps in the absence of potassa, an acid is used of

which each alkalimetric division is equivalent to one grain of soda; and, therefore, when the amount of soap taken for the assay is one hundred grains, the number of measures of acid required to effect neutralization at once indicates the percentage amount of soda contained in the sample. Such an acid is prepared by adding to each measure of concentrated sulphuric acid of specific gravity 1.8 to 1.84 about nine measures of water, and mixing thoroughly by agitation. When the mixture has become cool, its exact strength is ascertained, as follows:—One hundred and seventy-one grains of pure and dry carbonate of soda are taken and dissolved in water, and the solution is heated. The alkalimeter shown in Fig. 422 is then filled up to the point marked 0° with the mixture of acid and water, and sufficient of the latter is then poured into the solution of carbonate of soda to effect neutralization. The exact point is determined by testing, from time to time, with slips of blue litmus paper; and when the latter is tinged of a slight red color, the addition of the acid is discontinued, and the number of measures employed is noted. If the whole of the hundred measures are required, the acid is of proper strength; but if any less number have been added, it is then necessary to add more water, so that a hundred divisions shall exactly neutralize the hundred and seventy-one grains of carbonate of soda, this quantity being equal to, and indeed containing, one hundred grains of pure soda. This dilution, it will be observed, may now be effected with the greatest ease; for if ninety measures are required, then to each ninety measures remaining must be added ten additional measures of water, and the quantity of the latter required to be added is, of course, greater or less in proportion to the quantity of dilute acid employed, so that one hundred divisions shall contain only as much real acid as was before contained in the number of measures used. The acid being prepared, one hundred grains of the soap to be examined are dissolved in hot water, and the solution is filtered. The alkalimeter having been filled with acid, the latter is then poured into the soap solution until exactly saturated. The number of measures required at once indicates the centesimal amount of soda present. For the estimation of the alkali in soft or potassa soaps, an acid is generally used of different strength to that indicated above. This acid is of such strength that one hundred measures represent one hundred grains of pure potassa. Full directions for its preparation will be found under POTASSA, Vol. II., page 730. The process of estimation is performed exactly in the same way as for hard soaps. The test acid for hard soap may also be used to determine the alkali in soft soaps, simply by allowing for the difference in the atomic weight of the two bases. In this case it is only necessary to calculate for every ten grains of alkali found, 15.16 grains of potassa.

In Germany, America, and some other countries, soda and potassa are frequently both used in the production of hard soap. The determination of the amount of alkali in such instances is much less easily performed. The most convenient process is as follows:—A hundred grains of the soap are taken and dissolved in water, as before, and the solution is exactly neutralized by means of the soda test acid. By a simple calcula-

tion one may then ascertain the quantity of dry sulphuric acid which it has been necessary to add, for in every hundred alkalimetric divisions of acid are contained one hundred and twenty-nine grains of anhydrous sulphuric acid. The proportion of dry acid added being known, the solution is filtered to remove the liberated fatty acids, and the filtrate evaporated to dryness. The residue, consisting of the mixed sulphates of the alkalies, is then heated to redness, and after cooling, weighed. The weight of acid added, and that of the mixed sulphates being known, the relative proportion of each alkali contained in the soap may then be easily calculated; for as one hundred parts of sulphuric acid give 177·5 of sulphate of soda, and the same quantity of the acid gives 217·5 of sulphate of potassa, if the weight of the dry sulphate obtained exceeds the ratio 100:177·5, the excess is due to the salt of potassa, from which the proportion of pure potassa may now be ascertained, since eighty-seven parts of sulphate of potassa represent forty-seven of potassa.

The amount of foreign matters—that is, substances other than fatty matters, alkali, and water present in soap—is determined by taking a weighed portion, and after having reduced it to thin shavings, treating them with boiling alcohol. A white soap should dissolve completely, and a mottled soap should not leave more than one per cent. The exact amount of the residue is determined by weighing it; its nature is ascertained by treating it with cold water, by which the soluble salts are extracted, and the proportion of these is estimated by evaporating the liquor to dryness. The residue unaffected by the cold water, is then treated with boiling water. The presence of starch or fecula is now recognized by the appearance of a more or less thick gelatinous mash. The filtered solution, upon the addition of a little iodide of potassium and nitric acid, or a bubble of chlorine, if starch be present, becomes violet blue. The insolubility of the residue in either hot or cold

water, denotes the presence of lime, clay, *et cetera*. If lime, it is readily soluble in hydrochloric acid, and upon the addition of ammonia and oxalate of ammonia to the solution, a white precipitate appears. What remains unaffected by alcohol, acid, and water, is clay, silica, pumice-stone, *et cetera*. The presence of an alkaline silicate in soap is detected by dissolving a portion in water, neutralizing by means of dilute hydrochloric acid; if the silicate is present in moderate quantity, silicic acid at once falls, and may be easily recognized. When it exists in lesser proportions the fatty acids should be removed by filtration, and the filtrate then evaporated to dryness, and the residue treated with water; if silica be present, it will remain as a white gritty powder, and may be collected, dried, ignited, and weighed.

It not unfrequently happens that a soap contains more or less uncombined or non-saponified fatty matters, and in this case, when the soap is dissolved in water, a film of oily matter is seen to float on the surface. MORFIT gives a method for determining the amount of this as follows:—The aqueous solution is decomposed by means of hydrochloric acid, when the fatty acids as well as the unaltered fatty matter collect together on the surface of the liquid. These are separated by filtration, thoroughly washed, and then treated with caustic baryta. The precipitate produced is thrown on a filter, washed with boiling water, and then acted upon by hot alcohol. By this means, the non-saponified grease dissolved is from the soap of baryta, and after separation of the alcohol by evaporation, its weight may be ascertained. When tested by litmus paper, it should not show an acid reaction. In the appended table, the great discrepancies in the value of different kinds, of soap are clearly pointed out; yet it must be noticed that the portion of alkali in combination with the fatty acids was not separated in the analysis from that portion contained in a free state—for instance, as lie:—

Variety of Soap.	Fatty Acids.	Dry Potassa.	Dry Soda.	Water.	Common Salt.	Analyst.

There are several other important considerations relating to the determination of the value of soaps, besides what is revealed by analysis. As KNAPP observes, the consumer should not be satisfied with a soap in which the amount of the dry fatty alkaline compound accords with the price, unless the soap fulfils another condition of equal importance. The problem to be solved by the soap boiler, is the production of an article from which no more is dissolved or washed away, when it is employed as a detergent, than is absolutely necessary for cleansing purposes. When this is not the case, much soap is uselessly wasted. This property of soap is carefully watched by the laundress; and for purposes of domestic economy, the quantity of soap employed is much more materially affected by it, than by the state of the articles to be cleansed. If the soap contain too much water, or its consistence be rendered too loose by reason of an excess of lie or salt disseminated through it, as is the case with many of the varieties of soap described, the waste from this cause will be proportionately great. On the contrary, if the soap is over dry, much laborious exertion will be required to detach a sufficient quantity for the purposes required. Curd soap is the only kind which maintains the proper mean between these two opposing characters, and this is due to the quantity of water which it contains, and its state of solidity. Soap that has become too dry, is improved by being kept in a moist place, and an opposite treatment improves soap that contains too much water. But, of course, as regards the foreign salts they contain, no alteration or improvement can take place. Curd soap is therefore the proper form in which soap should be sold; no deception need however be practised, when soap containing a large amount of water, as that from coconut oil is manufactured, provided a corresponding reduction be made in the price. The same applies to soap prepared from bones, fuller's earth, silica, *et cetera*, which, if they cannot positively be called adulterations, are very much calculated, like the former, to promote dishonest traffic. The production of these articles will find very little encouragement when the soap boilers understand their own interests and responsibilities. These remarks, of course, do not apply to soft soaps which are used for entirely different purposes, and in a different manner.

USES OF SOAP.—Soap is applied for washing, for fulling woollen cloths, *et cetera*, and in medicine. Its application for washing is founded on two conditions, namely, on its power to remove fatty matters from textile and other materials, and to form therewith an emulsive mass soluble in soapy water; and on the readiness with which the neutral salts of fatty acids are decomposed by warm water into acid compounds and free alkali. The latter acts upon the impurities of substances, and forms with them compounds partly soluble, and partly such as will no longer adhere to textile fabrics and other bodies, whilst the separated acid salts of the fatty acids keep the surface of the material in a smooth condition.

STATISTICS.—The manufacture of soap is carried on more extensively in the United Kingdom than in any other country of the world. The number of manufac-

turers has gradually decreased since the year 1801, when there were six hundred and twenty-four. In 1811 the number was five hundred and twenty-two; in 1845, three hundred and fifty-six; and in 1850, three hundred and twenty-nine, besides sixty-eight remelters or perfumers. But, notwithstanding this decrease in the number of makers, it is almost needless to say that the quantity of soap produced was greater each year, and since the remission of the duty, has increased in still greater proportion. The quantity made in Great Britain in 1850, amounted to ninety-one thousand two hundred and fifty-five tons. Of this quantity five thousand six hundred and five tons were exported to foreign parts, and there were therefore detained for home consumption eighty-five thousand six hundred and fifty tons. Of this ten thousand two hundred and four tons were consumed by manufacturers of woollens, silks, and cotton. After deducting the quantity exported, and that used by manufacturers, it appears that seventy-five thousand four hundred and forty-six tons were employed for domestic purposes in Great Britain, a quantity equivalent to eight pounds and one ounce to each person. In 1851 the quantity manufactured in Great Britain amounted to ninety-one thousand nine hundred and fifty-three tons. Of this quantity England produced eighty-one thousand five hundred and sixty-nine tons, and Scotland nine thousand nine hundred and eighty-four tons. In 1852 the quantity manufactured was ninety thousand six hundred and sixty tons. In England the quantity is made up, of *hard soap* seventy-five thousand three hundred and seventy-eight tons; of silicated soap, five hundred and ninety tons; and of *soft soap*, five thousand six hundred and one tons. The nine thousand nine hundred and eighty-four tons produced in Scotland, consisted, of *hard soap* six thousand seven hundred and eighty-eight tons; silicated soaps, three tons, and of *soft soap*, three thousand one hundred and ninety-three tons. The quantity imported into Great Britain in the above year, was—from foreign countries, one thousand five hundred and thirty-three hundredweight three quarters of Naples soap; from Ireland fifty-two tons seven hundredweight of hard soap, and twenty-seven hundredweight ten pounds of soft soap. The quantity of soap produced in the latter country cannot be ascertained, as there having been no duty levied upon it, no returns were required. The annual revenue derived from the soap manufacture in Great Britain in the last years the duty was levied, exceeded one million pounds sterling. It was entirely remitted in 1853.

The following, the Editor understands, are among the largest and best soap factories in the three kingdoms:—The West of England Soap Company, Plymouth; Mr. JOHN WHEEN, London; Messrs. TYSON and RICHMOND and Mr. WILLIAM MOORE, Liverpool; Messrs. WILKIE and SOAMES, East Greenwich, London; Messrs. J. BARRINGTON and SONS, Dublin; Messrs. HOWE and Company, Old Brentford; Messrs. CHARLES TENNANT and Sons, Glasgow, *et cetera*.

SODIUM.—*Sodium*, English and French; *Natrium*, German and Latin.—This is one of the metals discovered by SIR HUMPHREY DAVY, through the agency of voltaic electricity. Moistened hydrate of soda was employed, and the oxygen both of the water and of soda was liberated at the positive pole, and the sodium of the oxide at the negative pole.

About the same time, 1807, were discovered also potassium, barium, strontium, and calcium, and, besides, traces of metallization were also obtained from the earths. The compounds of sodium with other substances are of great importance in the arts and manufactures; for example, it enters into the composition of common salt, of sulphate of soda, and of the carbonates of soda—substances so important as articles of commerce, owing to their daily employment in domestic economy, in the manufacture of glass, of soaps, in bleaching, and in numerous processes of manufacture little less important. Sodium itself, too, has lately become of great interest, and its preparation, it may safely be predicted, is destined shortly to occupy a position amongst the useful arts scarcely less important than the extraction of iron from its ores. As a metal, owing to the great facility with which it becomes oxidised, it is never likely to be much employed; but it is this very property of rapid oxidation which has caused it to be applied in the liberation of other metals from their combinations; and, from the extreme cheapness of carbonate of soda, and the facility with which sodium may be obtained from this salt, it would be doubtless possible to procure it on the large scale at a price little, if at all, higher than that of zinc.

PREPARATION.—The processes already described for the production of potassium are applicable also, with slight modifications, for the preparation of sodium. The apparatus required is also of exactly the same description as in the case of potassium. The substances employed are either hydrated soda and iron, or carbonate of soda and charcoal. These are placed in a malleable iron bottle—those in which mercury is imported answer admirably—and heated to whiteness in a powerful wind furnace. The gas, which after some time makes its appearance, is conducted into a receiver of iron or copper containing mineral naphtha or rock oil, and which receiver is kept cold by surrounding it with cold water, which is frequently changed. It should, of course, be provided with a vent for the escape of the incondensable gases evolved during the decomposition. The operation is much more productive than in the case of potassium, owing to the fortunate circumstance that sodium does not combine with carbonic oxide.

It appears, nevertheless, that the decomposition either of hydrate of soda by metallic iron, or of carbonate of soda by charcoal, is effected with greater difficulty than is the case with the corresponding potassa salts. It appears also, that by mixing the soda or carbonate of soda with a little potassa or carbonate of potassa, the operation is effected with greater facility, but the metal obtained is then a brittle alloy of sodium and potassium. From this, however, the whole of the potassium may readily be separated by means of slow oxidation, without any considerable loss of sodium. To

effect this, the alloy obtained is founded into plates, and placed in a large bottle; these are covered with naphtha, and the air in the bottle is occasionally removed. After a few days the whole of the potassium will have disappeared, and pure and very ductile sodium remains. The process usually employed in the preparation of sodium is that recommended by SCHOEDLER. The carbonate of soda used is obtained by the ignition of acetate of soda, free access of air being avoided. The object of this is to obtain the carbonate in a very pure state, since, if sulphate of soda be present, it becomes reduced in the process to sulphide of sodium, which acts strongly on the iron bottle. The mixture of carbonate of soda and charcoal obtained is to be mixed with a fourth of its weight of charcoal in fine powder, and with double this quantity of charcoal in a coarse state, to prevent fusion of the mass, which, should it occur, the fused contents spirt into the tube, and choke it up. This mixture, heated in the iron bottle, yields pure sodium, with very little black residue.

The proportion of sodium obtained by the author of this process was, from three pounds of the commercial acetate, about four and a half ounces of sodium; but in the laboratory at Giessen, even when it was obvious that the result was capable of considerable improvement, three pounds of acetate yielded nearly five ounces of sodium, the whole of the sodium present being about seven ounces. To remove the impurities from the globules of sodium, SCHOEDLER directs them to be pressed through strong and not very fine linen, the metal being first heated in naphtha to the boiling point.

PROPERTIES.—Sodium is of a silver white color; its lustre is more brilliant than that of lead, but scarcely equals that of silver. At the ordinary temperature it is solid, but soft and ductile like wax. At 4° it is rather hard, at 32° very ductile, at 120° it is semifluid, and at 194° perfectly so. Though less fusible than potassium, it is more readily volatile, and hence a less intense heat is required in its preparation. When exposed to the air it quickly becomes tarnished, owing to the formation of a crust of soda; and if heated nearly to redness, it inflames, and emits brilliant scintillations. The specific gravity of sodium is 0.972 at 60°, and it is consequently lighter than water, and if thrown into this liquid exposed to the air it swims about, presenting the appearance of a silvery-fused globule, constantly decreasing in size and producing a hissing noise, owing to the escape of hydrogen gas. These phenomena continue until the whole is dissolved as soda.

Potassium under the same circumstances takes fire, and continues to burn until dissolved; but sodium, in decomposing water, either produces less heat or requires a higher temperature to inflame it. If, however, the water be thickened with gum, so as to retard the movement of the sodium over the surface, or if there be only a few drops of water, the metal then ignites.

Sodium, like potassium, decomposes most oxides, metallic and non-metallic; also by far the greater number of salts, deoxidising not only the acid but the base also, if it happen to be oxide of a heavy metal. When thrown upon the surface of mercury, sodium

forms an amalgam, with the production of heat and light; this does not take place with potassium. Sodium is employed in the arts, principally in the preparation of aluminium, by the decomposition of the chloride of that base.

OXIDE OF SODIUM.—SODA.—When sodium is burned in dry air or in oxygen a white powder is formed, which attracts moisture and carbonic acid from the atmosphere. This is the *protoxide* of sodium— Na O . It is very similar to the protoxide of potassium, but may be known from it by the following properties:—When exposed to the air at the ordinary temperature, it first attracts moisture, becomes liquid, and, after further exposure, again solidifies; the protoxide of potassium, however, always remains moist. The other oxides of sodium are the *suboxide*— $\text{Na}_2 \text{O}$ —which is a greyish-white dull brittle mass, more combustible than the metal itself; and the *peroxide*, which is a dirty greenish-yellow substance, supposed to have the composition Na O_3 , but, never having been obtained in the pure state, this of course has not been proved. Neither of the oxides of sodium *per se* have any application in the useful arts, but the combination of the protoxide with water, namely hydrate of soda, sometimes termed simply soda, and also known as caustic soda, is an article of very great importance. It was known probably at a very early period, though, up to the time of the discovery of the alkaline metals, this and the hydrate of potassa were regarded as anhydrous alkalies.

PREPARATION.—The hydrate of soda is usually obtained by decomposition of the carbonate, by means of quick or hydrate of lime. To a boiling solution of five and a half parts of crystallized carbonate of soda, in twenty parts of water, a quantity of milk of lime, prepared by treating one and a half parts of burnt lime with four parts of warm water, is added in small portions at a time, and the mixture is boiled, with the addition of more milk of lime, until the filtered solution ceases to effervesce on the addition of an acid. The decomposition is expounded in the annexed equation—

By evaporating the solution to dryness, a hydrate of soda is obtained, which, however, usually contains traces of silicic acid, aluminacic, and phosphoric acid. These impurities may be removed, except a minute trace of alumina, by treating the solid hydrate with alcohol, in which the soda salts of those acids are insoluble. In evaporating the alcoholic solution, it is necessary to add a little water from time to time to prevent blacking of the mass. Probably the purest hydrate of soda is procured by decomposing the pure sulphate by means of hydrate of baryta. The soda salt being dissolved in water, the hydrate of baryta, also in solution, is added as long as precipitation ensues. The clear solution decanted from the precipitate and carefully evaporated to dryness, yields a mass of hydrate of soda perfectly free even from alumina.

PROPERTIES.—Hydrate of soda is a white opaque brittle substance, of a fibrous texture; it fuses below

redness. In properties, it greatly resembles the corresponding salt of potassa, but is less volatile at a red heat than this salt. When exposed to the air it rapidly attracts moisture, becomes liquid, but soon dries up again; the mass becoming converted into carbonate, which, unlike the carbonate of potassa, is not deliquescent. A solution of hydrate of soda, which is very caustic and powerfully alkaline, dissolves wood, hair, the skin, and most animal matters; tallow and other unctuous substances, with formation of soaps; sulphur, and some metallic sulphides; silica, alumina, and several metallic oxides quite insoluble in water.

The following table, constructed by ZIMMERMAN, shows the quantity of soda— Na O —in alkaline menstrua at different densities:—

QUANTITIES OF SODA IN A SOLUTION OF SODA AT 15° CENTIGRADE—59° FAHR.—BY ZIMMERMAN.

Solution of caustic soda constitutes the soda lie of the soap manufacturer, and is usually prepared on the spot by decomposing carbonate of soda or *soda ash* by means of lime. The mixture is placed in large cast-iron vats and covered with water, and after some hours the lie is withdrawn through a plug at the bottom of the vat, and either fresh water or a weak lie introduced at top. Full directions for the proper performance of the process are given under the article SOAP.

The solution of soda so prepared is contaminated with the common salt, sulphate of soda, and other constituents of soda ash; these may, however, be separated in great part by concentrating the solution considerably, these salts being insoluble in a strong solution of soda. A very useful article has lately been introduced by some alkali manufacturers, intended to supersede the use of the soda ash in the soap manufacture, and in other processes of fabrication in which caustic alkali is employed; and considering the advantages likely to ensue on its introduction, and the great simplicity of the process of production, it is a matter of surprise that its preparation on the large scale has been so long delayed. The article in question is a very pure solid caustic soda, containing hydrate of soda to the amount of nearly eighty per cent.

Probably the oldest method of producing caustic soda on the large scale, though it was applied as a preliminary to the preparation of the carbonate of soda, is that originally discovered by SCHEELÉ. It consists in the decomposition of chloride of sodium by means of protoxide of lead or litharge. This method was employed in England by Mr. TURNER, and in France by CHAPTAL and BERARD, for producing, besides caustic soda, the fine yellow pigment designated *patent yellow*; the operation was performed by intimately mixing and rubbing together one part of salt and from four to six parts of litharge, and a little water. Double decomposition takes place between the salt and a portion of the oxide of lead, with formation of caustic soda and chloride of lead, as shown in the annexed equation:—

The latter salt afterwards unites with a portion of undecomposed oxide of lead, and remains as an insoluble oxychloride of lead. About twenty-four hours are required to complete the decomposition, during which time the mixture is to be constantly agitated. It is then allowed to stand a few hours to settle, and the solution of caustic soda is then decanted, the residue well washed with successive portions of water, the washings being used in the preparation of a fresh quantity. The decanted solution on evaporation yields a very pure hydrate of soda, and the lead compound, after being dried and fused, becomes of a beautiful yellow hue. The decomposition of the common salt is in this process very complete; but owing to the high price of litharge, and the limited sale of the pigment, the method has been generally abandoned as a manufacturing process.

The attention of manufacturers was first directed in 1853, by Mr. GOSSAGE, to a source of caustic soda, from which it may be obtained with great economy and by a very simple method. This source is the liquor obtained by lixiviation of black ash or ball soda, a compound which will hereafter be minutely described. The chief object of the manufacture, of which black ash is an intermediate product, is the preparation of carbonate of soda—that salt which is contained in the largest proportion in black ash liquors—and one of the principal advantages of this method of procuring caustic soda, is that by its separation from black-ash liquors, the carbonate is obtained in a considerably pure condition. The liquor resulting from the lixiviation of black ash contains carbonate of soda, sulphate of soda, and caustic or hydrate of soda, chloride

of sodium—a deep-reddish compound of sulphide of sodium—and a few other substances, in very minute quantities. When the menstruum is concentrated by boiling, crystals of monohydrated carbonate of soda separate; and if the evaporation be continued the whole of the carbonate falls in this state and can be readily separated, leaving a reddish or sometimes a blackish lie, the principal constituent of which is caustic soda. On further concentrating this mother-lie to a certain point, and adding an oxidising agent, the double sulphide of sodium and iron is decomposed, and the solution loses its deep color; any sulphates or other compounds which separate during the concentration are removed; and there remains a liquor, which in boiling to the necessary degree, affords an almost perfectly white solid hydrate of soda, contaminated with only a very small proportion of other matters. In GOSSAGE'S specification, which will be alluded to more in detail in connection with the improvements in the manufacture of *soda ash*, he directs the black-ash liquor first to be exposed to the air, so as to absorb oxygen therefrom, the effect of which is to destroy a great proportion of the double sulphide contained in such lie, and, consequently, the removal of much of the coloring matter. To the menstruum so purified he gradually adds a solution of chloroxide of calcium or bleaching powder, in order to convert any hyposulphite of soda which may be present into a sulphite or sulphate of soda; he then concentrates the liquor by evaporation, and removes the whole, or nearly the whole, of the carbonate of soda and other salts, and afterwards continues the evaporation till, on cooling, a solid mass of hydrate of soda is obtained.

Prepared according to the directions given above, the caustic soda is still very highly colored, and would certainly be objected to by most consumers of this article. By a modification of the process, however, the hydrate may be obtained white, or with only the slightest possible tint; and this improved process is now generally employed by alkali manufacturers. The liquor, after the separation of the greater portion of the carbonate of soda, is conveyed to an iron boat-shaped pan, and further concentrated to remove the remainder of the salts present. Whilst the liquor is in a state of ebullition in this pan, and at a density of 1.50, nitrate of soda is added in sufficient quantity to effect the decoloration of the fluid; this salt yields oxygen to the sulphide, and converts it into sulphite, in which the sulphide of iron is insoluble; whilst its nitrogen is liberated in the form of ammonia, and the base is set free in the fluid. Thus—

The liquor is drawn off from the forementioned pan after the salts have deposited, which happens in a period of four hours' repose, and transferred to another pan or pot, and the evaporation continued till the liquid readily solidifies on cooling. From half to one hundredweight

of the nitrate of soda is sufficient to purify such a quantity of liquor as will yield one ton of caustic soda.

A process in which caustic soda is produced was patented some years ago by Mr. WILLIAM HUNT, the principles of which were briefly as follows:—When the

product of the decomposition of sulphate of soda by coal or coke is lixiviated with water, and the solution which contains sulphide and bisulphide of sodium with caustic and carbonate of soda, is boiled with oxide of zinc or black oxide of copper, double decomposition ensues between the sulphide of sodium and the oxide of copper or zinc, and sulphide of either of the metals results, with caustic soda in the solution. The metallic sulphide thus produced is made available in the preparation of another quantity of sulphate of soda from common salt, by a process which will be described in treating of the preparation of sulphate of soda. It has been proposed also to procure caustic soda directly from the sulphate, by decomposing this salt by means of a solution of hydrate of baryta. When a solution of sulphate of soda is mixed with one of caustic baryta, changes ensue as in the annexed equation:—

Sulphate of baryta is insoluble; and, therefore, if the mixture be made in proper proportion, nothing remains in the solution but caustic soda. The difficulty of procuring with facility the requisite quantity of caustic baryta, will probably always prevent this process from becoming general. The process for the production of caustic soda on the large scale from black-ash liquors is so convenient and economical, that it will probably be never entirely superseded. If there be a demand for greater quantities than can be obtained from this source, the carbonate of soda in black-ash liquors must be converted into caustic soda by the addition of lime, and the caustic soda then separated as previously described.

Caustic soda is indeed now produced on a very large scale; and from a consideration of the advantages likely to ensue, as its use becomes more general amongst manufacturers requiring alkali, a very great increase on the present demand may certainly be expected. It is to the soap manufacturer that the introduction of this salt will prove to be the greatest stimulus the trade has received since the introduction of artificial soda; indeed, the soap manufacture will be so greatly simplified by the use of this salt, that the present mode of production may be expected in a short time to be entirely abandoned.

CHLORIDE OF SODIUM—*Common Salt, Sea Salt, Muriate of Soda; Chlorure de Sodium*, French; *Kochsalz*, German.—This substance possesses a peculiar interest, from its being one of the usual and necessary constituents of food; whilst the enormous consumption in the arts, and the variety of purposes to which it is applied in manufacturing operations, invest the study with an importance second to none. Salt is the longest known compound of sodium. As early as the time of the destruction of Sodom and Gomorrah mention is made of it in connection with the judgment against Lot's wife, *and she became a pillar of salt*. In Leviticus it is alluded to as a preservative and a component of the prescribed sacrifice. In the gospels of the New Testament its preservative qualities are

beautifully inferred from CHRIST's testimony and charge to the Apostles—*Ye are the salt of the earth, but if the salt lose its savor wherewith will it be salted*. Salt, it is said, appears in the sacred volume as the emblem of eternity, of repentance, of reconciliation, and of wisdom. NUMA among the Etruscans, and PYTHAGORAS among the Greeks, repeated the precept of MOSES—*Do not speak of Deity without fire; nor sacrifice without salt*. PYTHAGORAS calls it *a substance dear to the gods*; HOMER designates it *divine*; and PLUTARCH remarks, *it symbolizes the soul*. Salt has always been, and is now, with the Arabs, the emblem of hospitality. It figures largely in Eastern story. A thief, for instance, entering an Arab's tent at night while the master is asleep, seizes some food and becomes aware of the flavor of salt; bound involuntarily by the laws of hospitality, he withdraws, without carrying out his felonious intention. In the story of the Forty Thieves, the chief robber, who enters the house of MORGIANA's master on a false pretence, is enjoined to make such excuses whenever his host offers him salt as will enable him to refuse partaking of it without suspicion.

It would be interesting if one could learn the secret of the strange yearning mankind has for salt, which ages have not diminished nor civilization annihilated. Chloride of sodium occurs in every part of the human frame. It is organized in the solids and dissolved in the fluids; it creeps into every corner of the body, and plays a part in all the complicated processes of life, without which the machinery would be arrested in its operation. In England and America, the quantity of salt consumed gives twenty pounds per annum to each person; in France the average ranges about fifteen pounds; but in some countries the love of salt amounts to a mania. In Abyssinia every man carries a lump of salt; and when he meets a friend, he offers it to him to lick. Its use may be said to be almost as universal as water, and it may safely be regarded as among the most abundant mineral compounds in nature; certainly of all the minerals eaten, none can claim so high a place in science, history, and literature, and in the kitchen it is an indispensable condiment—

Even cooks would deem't a grievous fault,
Were viands eaten without salt.

When pure, chloride of sodium consists, in one hundred parts, of 59·67 chlorine and 40·33 sodium. It crystallizes generally in the form of the cube, the crystals usually being very perfect. It may, however, under particular circumstances be made to assume other shapes, but all closely allied to the cube. When a saturated solution in water is slowly evaporated, and the surface of the fluid kept perfectly still, the crystals as they form sometimes assume a very remarkable appearance. A cubical crystal first forms on the surface; other crystals as they grow attach themselves to the edges of the upper faces; the middle cube then sinks below the surface of the liquid, but is still held up by the lateral crystals, and the process goes on until a hollow square pyramid of considerable size, having its apex downwards, may thus be produced.

Chloride of sodium is only slightly more soluble in boiling water than in cold; according to POGGIALE:—

100 parts water at 32°	dissolve	35.52 of salt.
“ “ 57-2°	“	35.87 “
“ “ 212°	“	36.61 “
“ “ 229-46°	“	40.35 “

The last is the temperature of a boiling saturated solution of common salt, which will therefore deposit very little salt on being allowed to cool; but if there be some chloride of calcium or of magnesium present, the solubility of common salt at a high temperature rapidly increases, and a considerable crop of crystals of chloride of sodium may be obtained on cooling.

Common salt decrepitates when suddenly heated, owing to a small quantity of water becoming inclosed between the plates of the crystal, and its sudden expansion at a high temperature causing a fracture of the crystal. It melts at a low red heat, and may readily be volatilized in a hot furnace. The specific gravity of pure salt is 2.557. It has an agreeable and saline taste, and is slightly deliquescent in moist air.

There are two varieties of common salt in commerce—rock-salt, and the salt produced by the purification and evaporation of salt brines. Of the latter there are in England three qualities, differing not so much in their freedom from impurities as in the size of the crystals adapting them for special purposes in the arts.

ROCK-SALT.—*Native Salt, Mineral Salt, Sal Gem.*

—Rock-salt occurs as a regular mineral deposit associated with gypsum; its position is properly within the new red sandstone, but it has been met with in other situations. It occurs in layers varying in thickness from a few inches to several hundred feet. The rock is usually of a reddish-brown tint, and is rarely found colorless. The cleavage is cubical. Salt beds usually appear to have been formed by the evaporation of inland seas, the salt as it accumulated gradually filling up the bed of the sea or lake. The limited extent of these deposits, as compared with the stratified rocks over and under them, would seem to imply this. Indeed there are several instances of this kind of deposit in process of formation in various parts of the world. Thus the bed of the Dead Sea is gradually being filled up with such a deposit, and a leaden plummet dropped in deep water will bring up with it crystals of remarkable size and beauty, and at the same time almost chemically pure; but there are several lakes distributed over the globe in which the water is either quite or very nearly saturated with salt. In Asia and Africa there exist basins of sand, from which salt water has evidently been removed by evaporation, leaving the bed of the basin covered to some depth with salt; indeed, in the neighborhood of the Red Sea, and Salt Lake in Western America, every considerable depression of the soil is more or less incrustated with salt. The mines of rock-salt, most probably originating in the manner described, are not found at any determinate elevation. Thus, the great deposit extending from Upper Austria through Salzburg, is found at an elevation exceeding three thousand feet above the level of the sea; the saline rock of Arbonne in Savoy is seven thousand two hundred feet above sea level; and the immense accumulation in the Saletres of Peru, where the

salt is associated with nitrate of soda, three thousand feet; while that in Wieliczka in Poland is eight hundred and sixty feet below sea level. All these beds, like other mineral deposits, are intersected by faults, and broken up by the upheaving and subsiding of the earth; but from their limited extent, the continuity of the bed is less frequently observed to be affected.

The great deposit of rock-salt that furnishes most of the salt used in England exists in Cheshire. The broad valley extending from near Malpas to Congleton, sweeping in the form of a crescent between the red-sandstone hills of Shropshire and the Staffordshire coal field on the one side, and the high ground of the Peckforton hills and Delamere range on the other, appears to be occupied by the saliferous and gypsiferous beds, lying as it were in a trough, to which the adjoining portions of both the above ranges dip. There are several faults and dislocations in this field; thus, at Lawton, rock-salt is found two hundred and ninety feet above sea level, while at Winsford it occurs ninety feet below, and at Frodsham Bridge no salt was found at four hundred and fifty feet below sea level. The continuity of the bed is frequently broken in the course given; and perhaps the number and depth of borings might to some appear insufficient to establish the extent of the bed; but the existence of the rock where it has not actually been reached, is ascertained with equal certainty by the peculiar sinking of the overlying ground, due to the withdrawal of the brine. The gypsiferous and saliferous beds at Northwich and Middlewich, where alone one has satisfactory information respecting them, may be estimated to be on an average seven hundred feet thick. The rock-salt lies in two beds principally. The depth to the first bed at Northwich varies with the undulations of the land, and also slightly with the irregularity of the bed itself, from ninety-six to one hundred and fifty-nine feet. At Winsford the depth is one hundred and eighty-nine feet. The thickness of the upper bed varies at Northwich from eighty-four to ninety feet in the pits sunk to the north-west, decreasing near the east border to eighty-one feet. It thins off towards the south-west, losing fifteen feet in thickness in the course of a mile. Below this lies a bed of indurated clay, thirty feet in thickness, and containing several thin veins of salt, and this overlies the second or great bed. At a pit at Marston, to the North of Northwich, this has been ascertained to be ninety-six feet thick. At Winsford, however, it is two hundred and twenty-five feet thick. At Northwich, the first sixty to seventy-five feet of rock are impure, the salt being contaminated with much clay and bituminous matter; in the next twelve or fifteen feet the salt is much clearer, and this portion only is worked. The clear portion corresponding to this is worked at Winsford at a depth of two hundred and ten feet in the rock.

The mining operations concerned in the getting of rock-salt hardly require any description. A shaft like that of a coal pit is sunk to such a depth as the position of the rock necessitates, and galleries are worked out from this. The rock is broken down by blasting, beginning at the top of the working and proceeding downwards. But little skill is required in supporting the roof from sinking in upon the miners, the rock being

so hard and firm that the galleries are worked from sixty to eighty feet broad without danger. As the rock gives off no gases injurious to animal life in any quantity, the usual great difficulty of ventilating the mines becomes easy; and sometimes the motion communicated to the air by the descent and ascent of the bucket in which the salt is wound up from the pit, is all the ventilation supplied for some months in the year.

Salt is, however, seldom found in mining operations of sufficient purity to be used in the arts, without being previously submitted to some process of purification. A pure and colorless salt is met with sometimes at Cardona in Catalonia, and in the mines of Wieliczka; and this is, therefore, simply cut into a convenient shape for the market. But most of the rock-salt mined is of a reddish hue, and contains a very small proportion of marl, a little bitumen, and a red coloring matter, analogous in character to the red fungous growth that appears on crystals of salt produced by the slow evaporation of sea-water. In addition to these impurities, rock-salt contains small quantities of various other salts, which impart to it a bitter taste, and make it deliquescent; among these are sulphate of soda and sulphate of magnesia, chloride of magnesium and chloride of calcium. But although rock-salt contains these impurities, it is a curious fact that the more deliquescent of these *are not contained in the rock as solid bodies*, but as saturated solutions in water inclosed in very minute cavities of the crystal.

Rock-salt from various mines is frequently observed to contain, pent up within its substance, a quantity of gas in a state of great compression. This phenomenon has been noticed in the rock from Wieliczka to a remarkable extent. In dissolving this salt in water a crepitation is heard, and this is occasioned by the sudden fracture of the walls of the crystal, when the gradual process of solution has reduced them so far that they are no longer capable of resisting the pressure of the inclosed gas. The gas evolved has been examined by M. DUMAS, and found to be nearly pure hydrogen. This gas may sometimes be heard blowing out in a mine like the light carbide of hydrogen of the coal mines; the quantity, however, is small, and it does not appear that an explosion has ever ensued from the incautious use of a candle.

It was customary to purify rock-salt in England formerly; but at present, salt brines of great purity and strength, and in unlimited quantity, may be obtained at so little cost, that recourse is now seldom had to the solution and subsequent evaporation of the rock. There is, therefore, little use for it, and most of the rock mined is exported. The quantity carried on the river Weaver, according to R. HUNT's report, from the 5th April, 1857, to 5th April, 1858, amounted to sixty-five thousand seven hundred and seventy-three tons.

There exists a large field of salt in Worcestershire, of which the principal bed lies three hundred feet below the surface of the ground; but the rock itself is not worked, and owing to a deficiency of borings, the geological characters of the deposit have not been so thoroughly studied as is the case with the Cheshire field. The whole of the salt prepared in the county is made by the evaporation of strong brines.

There is no country so favored in respect to the abundance and ease with which common salt may be procured as is England; and as this substance is a necessary of life, it sometimes happens that it becomes requisite in countries not so favored, to carry on the manufacture by the evaporation of very weak brines, and even of sea-water.

The following analysis may be considered to be the mean composition of the water of the ocean:—

ANALYSIS OF SEA-WATER.

OBTAINING SALT FROM SEA-WATER.—In consequence of the small proportion of salt existing in sea-water, direct evaporation by means of fuel is never had recourse to in the preparation of common salt from this source. Slight variations are observed in the results obtained by various chemists as to the actual amount of salt in sea-water; but these discrepancies are most probably due to the influence of local causes and climate. The actual amount in the water of the Mediterranean is 2.7 per cent., as near as possible. Sea-water is always brought to a certain degree of concentration by placing it under such circumstances that it shall be most favorably affected by the drying influence of the atmosphere; and, as will be readily understood, the actual method of proceeding will vary greatly in accordance with the character, the climate, and the actual position of the works. Thus, in the South, where evaporation is rapid and the condition of the soil favorable, the sea, at the rising of the tide, is allowed to run through sluice-gates into a pond covering about an acre or more of ground, and about six feet deep. When full the gates are closed, and the water gradually deposits all the mud and matters in suspension. From this reservoir the clear water is conducted by pipes into a series of shallow basins, the whole covering some acres of ground, where, by exposing a very large surface of water to the drying influence of the sun and air, it rapidly evaporates. These basins are so arranged that the water shall flow slowly from the first reservoir downwards through the whole series, and the flow so regulated, that by the time the water arrives towards the last basins, it shall be in such a state of concentration as to deposit crystals of salt. A certain redness appearing on the surface, due to a fungous growth, is a good indication of the degree of concentration of the liquors, and its appearance is accompanied by the crystallization of the salt. The crystals as they fall are raked out at certain intervals and collected in small heaps on the ledges separating the basins one from the other. As soon as the mother-liquors begin to deposit salts of magnesia and sulphate of soda, they are run away into the sea, or they are allowed to flow into another series of evaporating ponds, to be there treated in such a way as to separate the sulphate of soda and other

salts contained in sea-water from the common salt still remaining in them.

The manufacturing process will be best seen by a reference to the woodcut—Fig. 509. A is the large reservoir into which the sea is allowed to flow at high tide through the gate, o. From this it flows through a pipe into the long canal, B B C. The flow of water is very slow, and is regulated by means of the supply pipes. The sea-water then enters the reservoirs, D D, in which the water assumes a green tint, due to the growth of conferva; these die, however, when the brine attains a specific gravity above 1·040. From the reservoirs, D D, the brine flows through the channel, E E, into the divisions, where it deposits a considerable quantity of sulphate of lime; this takes place when the brine is of a specific gravity between 1·116 and 1·145, and when it attains a specific gravity of 1·210 it no longer contains a trace of sulphate of lime—this salt being insoluble in a solution containing much sulphate of magnesia. The brine is now let into the

compartments, g g, where it begins to deposit common salt. The depth of liquid on these beds is not much above two or three inches, and is renewed every two or three days, according to the state of the weather. The brine is allowed to concentrate until it attains a density of 1·263, when, although the whole of the common salt has not been removed from it, the liquors are allowed to run out on the crystallizing tables as they are called. The salt as it deposits forms a hard incrustation on these tables, which, during the five or six months the operation is conducted, attains a thickness of about three inches. The mother-liquors are now run off the tables, and the salt scraped up and collected into small heaps, p p, to drain. These are collected together into larger heaps, m, n, and covered with straw in the form of a haystack to protect them from the rain. They are then allowed to remain for some time, that the moisture of the atmosphere may gradually remove the more deliquescent salts, consisting of the chlorides of magnesium and calcium.

Fig. 509.

The product obtained in the manner described is contaminated with clay from the bottom of the ponds, and it therefore requires to be purified by dissolving it in water, separating the clay by subsidence, and evaporating the solution to dryness. The manufacture of common salt on the plan described is carried on only during the summer months, that is, from March to September. The value of the process, of course, altogether depends upon the state of the atmosphere, and it frequently happens that a continued moist condition of this altogether arrests the evaporation.

The manufacture of salt, as described, is extensively carried on in France and Spain, and all parts bordering on the Mediterranean, and was formerly practised in England, particularly at Lymington in Hants.

In Russia, salt is manufactured by allowing sea-water to freeze, and removing the ice as it forms. The success of this process depends upon the fact, that when

sea-water partially freezes, the ice formed contains proportionately less salt than the remaining water; the mother-liquor, therefore, by repeating this process of congelation, becomes more and more impregnated with salt, until, indeed, a saturated solution of brine may in this way be formed.

Dr. WALKER, from experiments made in the Polar Seas, found that at 28·5° sea-water begins to freeze, and as the process of congelation went on he observed a saline *efflorescence* to form on the surface of the ice; but when the ice had attained a considerable thickness this efflorescence was not observed to increase, and Dr. WALKER concludes that the excess of the salt was then precipitated. It may be remarked that, according to Dr. KANE, if the cold be sufficiently intense, the water produced by melting the ice will be so far free from salt as to be fit to drink. In Dr. WALKER's experiments, however, the purest specimen of water obtained

by melting the ice formed at 42° was of specific gravity 1.005, and afforded abundant evidence of the presence of common salt, and in quantity sufficient to make the water unfit for most domestic purposes. The

salt obtained by the evaporation of the mother-liquors, as described, is however very impure, containing many of the foreign salts present in sea-water, as will be seen from the analysis as under:—

ANALYSIS OF SPECIMENS OF RUSSIAN SALT PRODUCED BY THE FREEZING PROCESS.

	Salt from			
	The Sea of Okhotsk.	Salt works at Ouskout.	Salt works at Irkoutsk.	Salt works at Seleginsk.
Chloride of sodium,	77.60	74.84	91.49	74.71
Chloride of aluminium,	6.20	1.17	2.60	6.50
Chloride of calcium,	0.94	5.21	1.10	1.44
Chloride of magnesium,	1.66	3.57	2.05	3.55
Sulphate of soda,	13.60	15.20	2.76	13.80
	100.00	100.00	100.00	100.00

The salt obtained would have been of much better quality if such a quantity of milk of lime had been added to the concentrated mother-liquors as would have been sufficient to carry down the sulphuric acid, and to decompose the chlorides of calcium and of aluminium.

SALT SPRINGS AND WELLS—Brines.—When a fresh-water spring in its underground course passes

over a bed of rock-salt, it becomes more or less impregnated with that substance, and there results a salt spring or well. The amount of saline matter in salt springs, varies so much in character and quantity, as will be seen in the analyses given below, as to require a very decided difference in the method of treating them:—

ANALYSES OF SALT BRINES

Salt wells are made artificially by pumping water into an excavated salt mine. The saturation of the water with salt is effected; and yet the process of pumping in pure water and drawing out strong brine made continuous by letting down a pipe into the well, opening nearly but not quite at the bottom. The water in the pipe was always much below the level of the great bulk of water in the well, because the sole opening in the pipe being near the bottom, it only allows that to ascend in it which has become dense from the quantity of salt it has taken up; and thus, while pure water or weak brine is pumped into the well, only strong brine is pumped out of it through the pipe.

When the brines are very weak, they are always made to undergo a preliminary evaporation in the air; and when the presence of sulphates and the chlorides of calcium and magnesium are calculated by their quantity to impair the commercial character of the product, certain purifying processes are had recourse to by which these are removed. When carbonate of iron is present in the weak brine, it is generally got rid of by exposing the brine for some time to the air. The carbonic acid by which the iron is held in solution gradually escapes

into the atmosphere, and the carbonate of iron becomes converted into sesquioxide of iron, and falls. The muddy sediment, consisting of this and a little carbonate of lime, which also falls as the carbonic acid escapes, induces the growth of certain species of confervæ, and these impart an odor of decomposing organic matter to the water, which is, however, gradually removed in the subsequent operations. The process of evaporation with weak brines is carried on in France and Germany in what are termed graduating houses. These are large wooden structures from eight hundred to upwards of five thousand feet long by about forty feet broad, covered over at the top, and open at the sides to allow a free circulation of air through the interior. The roof covers and protects from the rain several very large but shallow wooden cisterns intended to receive the brine, or there may be only one cistern, divided by wooden partitions into several separate compartments, but the extent of these divisions, their collection under one roof, or their separation, are determined by circumstances purely local, such as the character of the water, or indeed the motive power available in distributing it. The several compartments are used to contain the brine

in different stages of concentration. The first is intended to receive the brine itself; the second to receive the same after it has been concentrated by exposure to the air in minute streams, *et cetera*. The position of these graduating houses is such, that they shall be exposed in the direction of their greatest length to the prevailing winds.

Various arrangements have been devised to increase the evaporating surface of the brine; but that which now supersedes all others consists in pumping the liquor up to the summit of a high reservoir, and allow-

ing it to trickle through the interstices of bundles of thorn built up in the form of a wall and supported by woodwork. This plan was first practised in Lombardy, thence introduced into Saxony, and in 1559 thorn stacks were used at Bavières; and the great advantages of the plan, over the thin inclined planes and long cords then employed on the continent, began to be fully appreciated and generally adopted. The particular apparatus used will be best described from the woodcut. In Fig. 510, A is the wall of thorns, usually from thirty to fifty feet high, and from one thousand two hundred to one

Fig. 510.

thousand five hundred feet long. It is supported by wood beams firmly secured at the base with masonry. The thickness of the wall is nine feet at the base, diminishing to six feet at the summit; B, is a large

cistern intended to receive the weak brine, and furnished with a number of small taps, C C, on either side, by which the brine may be distributed over either surface of the wall.

Weak brine is pumped up into the cistern, C, and the taps are opened on that side on which the wind prevails. The brine now slowly trickles through the thorn sticks, and from the large surface it thus exposes to the drying influence of the atmosphere the brine becomes rapidly concentrated. The brine, however, is never sufficiently strong by passing through only one stack; it is therefore pumped up again and allowed to trickle through another, and so on until the liquor has attained a particular degree of saturation, which is generally something between 22° and 32° Twaddell, depending upon the price or abundance of fuel in the locality. It is then ready to be evaporated by artificial heat.

On the thorn sticks there gradually deposits a scale, consisting of oxide of iron, carbonate of lime and magnesia, and sulphate of lime, and forming what is called *thornstone*. This incrustation at length attains such a thickness as to fill up the interstices between the sticks. The stack has then to be taken down, and the thorns renewed. This happens about every five or eight years, according to the character of the brine.

The rapidity with which water is evaporated by the use of thorn stacks is remarkable. Thus at Schönebeck the thorn surface is three hundred and ninety thousand square feet, and under very favorable circumstances evaporates 3·7 cubic feet during the twenty-four hours from each square foot. And from very careful experiments by BERTHIER, at his works at Moutiers, it appears that thirteen gallons of water are evaporated under ordinary circumstances every twenty-four hours from each square foot of thorn wall. It is a remarkable fact that the water evaporated from the thorn surface is practically proportional to the surface exposed, whatever be the density of the brine. Thus, from a series of researches made at Moutiers by the above eminent chemist, brine of specific gravity 1·010 was evaporated to 1·140, and tested at three different periods to ascertain the loss; and this, as the process of concentration advanced, is expressed by the numbers 10, 12, 11. Now, the excessive evaporation indicated during the last stage was undoubtedly due to the fact of the salt itself becoming volatilized; for the experiments of BERTHIER were conducted on a large scale, and independently of the quantity carried away bodily by the wind, one recognizes, by the sense of taste, a small quantity in the air, even when the process of evaporation is very gentle and regular. The same fact is shown in a manner more decisive in the thin incrustation of salt which may be seen on glass exposed in the vicinity of salt works; and the loss of salt from this source may be estimated at about ten per cent. The results, however, of BERTHIER's experiments show that practically the rate of evaporation between a strong and a weak brine is inappreciable; although, when the experiment is conducted with great care, so as to protect the surface of the liquid from rapid currents of air, Dr. B. G. BABINGTON has shown that the degree of concentration exerts a very decided influence in respect to the amount evaporated.

When the brine in the tanks under the thorn stacks has been brought to a specific gravity of between 1·14 and 1·16, it is run out into large settling reservoirs

with just sufficient lime to decompose the chloride of magnesium. These reservoirs are of immense capacity, for the evaporation in the air taking place only during the summer months, the reservoirs are made large enough to hold a great quantity of the concentrated liquor to be evaporated during the winter months. The eight reservoirs at Salza have a capacity of nearly three million cubic feet. In these reservoirs the brine deposits all suspended matters, and the clear liquor is then run into wrought-iron tanks to be evaporated to dryness. The process of evaporating the brine to the point of saturation is termed the *schlottage* of the salt. The further evaporation to obtain dry salt is termed the *soccage*.

SCHLOTTAGE.—The pans used in this operation are from about sixty to eighty feet long, by from twenty to forty feet broad, and two feet deep, and are made of thin sheets of wrought-iron rivetted together. Each pan is heated by two or even four fires, and the flues are so built that the heat shall be distributed over the whole bottom of the pan in a manner as effective as the brick supports for the pan will allow.

The pans being three parts filled with brine, and a little blood or grease added, are brought as rapidly as possible to the boiling point. A scum now forms on the surface, which is skimmed off. This scum consists of the organic matter in the brine, and a little bitumen, which is found in all brines from natural springs. In the meanwhile the brine, which is saturated with sulphate of lime, gradually deposits this on the bottom of the pan. When about one-fourth of the original brine has been evaporated, new brine of specific gravity 1·16 is again pumped in, and the process of boiling and removing the scum is continued until the brine in the pan has been brought almost to the point of saturation; it is then run into other pans of a similar shape, and about equal capacity, to be evaporated to dryness.

The deposit on the bottom of the schlotting-pan gradually attains a thickness calculated to interfere very materially with the conducting power of the iron, and so occasions much loss of heat; the pan has then to be scaled. Of course the necessity for performing this operation will vary considerably with the degree of purity of the salt. It is usual, however, to scale the pan after it has been filled up from eight to about fifteen times.

The deposit consists of sulphate of lime and sulphate of soda, inclosing mechanically a quantity of common salt.

SOCCAGE.—This operation is performed in wrought-iron pans, similar to those described before for the schlotting process. They inclose an area of about four hundred square feet. The bottom of the pan inclines a little towards the centre. Over the pan is a dome-shaped structure of wood, terminating in a kind of chimney, for the purpose of carrying away the vapor. The woodwork supporting the dome is open at the side, immediately over the pan, that there may be a free circulation of air over the surface of the brine. During the beginning of the boiling down the pans are briskly heated; towards the end, when much salt becomes deposited on the bottom, the fires are slackened, that the bottom of the pan may not be burned.

The process is continuous, the salt being taken out as it falls by means of scoops, perforated at the bottom, to allow the mother-liquor to percolate.

In the case of lime having been added in the settling pan, or at the beginning of the schlotting process, the mother-liquors do not become too impure to be evaporated down to dryness, even after the pan has been filled up with new brine several times. There is also an additional advantage experienced at this stage of the manufacture, from lime having been added to throw down magnesia, inasmuch as, during the process of evaporation, chloride of magnesium forms a crust on the surface of the liquid, which re-forms almost as soon as broken, thereby preventing very materially the escape of vapor. The formation of the crust, however, may be avoided equally well by the addition of a little sulphate of soda. An interchange of elements is thus occasioned; the sulphuric acid of the soda going to the magnesia to form sulphate of magnesia, and the chlorine of the magnesium passing to the soda to form chloride of sodium. The soccage pan requires chipping out about once a month or rather oftener.

Salt having been removed from the crystallizing pans by the strainers, is collected into larger heaps on a perforated floor to drain further; it is then transferred to the drying chamber. This is simply a long chamber, heated by the flues from the fires used to evaporate the brine. These flues converge into one or two main flues, which are made to pass along the bottom of this chamber. The salt is either packed up in shallow wicker baskets, or it is put into moulds, and these are piled up above the flue in the drying chamber, and there allowed to remain until the salt no longer loses much moisture, when it is fit for the market.

In England, all the salt prepared is obtained from the evaporation of strong brines by artificial heat. The brines used are saturated, or nearly saturated solutions of salt in water, containing from 23 to 26.5 per cent. of pure chloride of sodium, besides other constituents; while a saturated solution of salt in water only contains 27 per cent. of salt. Indeed, several experiments tend to show that some brine springs would seem to hold in solution more chloride than would be taken up by the same amount of water, however long it were left in contact with dry salt.

The brine springs of Cheshire do not rise to the surface of the ground. They emerge from the surface of the rock; and when the spring is tapped, will rise in the bore hole from eighty to ninety feet. In the neighborhood of Winsford and Northwich, a shaft is sunk in the ground six feet square, and about one hundred and eighty feet deep. The sides of the shaft are carefully boarded with planks, and an inner planking of six inch boards, four feet square, is then built in, and the space between the boards well puddled with clay, to keep out the fresh-water surface springs. The inner boarding is firmly built in, and made more secure by cross-stays of stout wood. An iron pipe about nine inches internal diameter is then let down into the boring. The brine will rise in this pipe about ninety feet; it has consequently to be lifted by a pump to about the same extent. A continuation of the pipe from the pump conducts the brine into a larger

reservoir lined with masonry. This reservoir, which may be about two hundred feet long by about sixty or eighty broad, and perhaps six feet deep, is not built for the purpose of allowing sedimentary matter to deposit, for the brine as it is pumped up is perfectly clear and free from particles in suspension. It is of a clear sea-green color, and the reservoirs are built to serve merely as a store of brine on a high level, and from which it may be drawn down to supply the evaporating pans as needed.

The evaporating pans are contained in a shed which may be four hundred feet long by about eighty feet broad, and about thirty feet high, open at the sides to permit a free current of air to pass over their surface. The pans are set in a firm foundation of brickwork, which does not, however, extend up the sides. There are generally four furnaces to each pan, and the flues, so built as to support the pan, radiate over the whole of the bottom. There are usually three pans in a series, under two of which furthest removed from each other are the fire-places. The flues passing under these are continued under the third, and meet in the centre, at which point they unite into one, and the flue is connected with the chimney; but so as to economize as much as possible the heat of the flue, a chamber is built over it in its course to the chimney, and this is made use of as a drying stove for the squares of salt.

The Cheshire brines, which are of specific gravity 1.200, and contain about 24 per cent. of common salt, are of so pure a quality that they require no preliminary februation. The brine is, therefore, at once run into the evaporating pans, which are of sizes varying with the source of heat, and evaporated by the direct action of the fire, or by the waste heat of the steam engine used to pump up the brine.

Those pans in which the salt is evaporated by a boiling heat, are about twenty feet square and eighteen inches deep. Those where a lower temperature is used, are about forty feet long by twenty broad, and two feet deep. The pans are made of quarter-inch iron boiler-plates rivetted together. They incline somewhat towards the end furthest removed from the fires, that more salt may be deposited on that part. The inclination is from six to eight inches in the whole length.

Three kinds of salt are manufactured in Cheshire; the difference, however, consists in the size of the crystal, depending upon the rapidity with which the evaporation is conducted. Thus the finest-grained salt is made by rapid boiling; the coarsest at a temperature of about 150°; and the medium quality between these two points.

The evaporating processes are conducted as follows:—Brine is run into a pan until it is three parts full; a little glue, and sometimes a little waste grease is then thrown in to assist in the formation of a scum, and partly to prevent the crystals of salt as they fall from adhering to the bottom of the pan. The brine is then brought to the boil as rapidly as possible, and a scum which forms on the top is removed by lightly skimming the surface with a piece of board. The crystals of salt begin to separate almost as soon as the brine is brought to the seething point, and when about half the

water has been evaporated fresh brine is run in. The salt that has boiled out is removed twice in the twenty-four hours. This operation is effected by a perforated scoop, and the salt is put into wooden moulds, or tubs, about eighteen inches high and nine inches broad at the top, and diminishing to about seven inches at the bottom. These tubs are put into the salt pan to be filled, and stand on a ledge on the side about six inches from the bottom of the pan. When the tubs are filled the salt is slightly pressed down, and the tubs are removed from the ledge on to a perforated floor, so that the mother-liquor may drain away from the salt. To allow of this there are two slits in the bottom of the tub. When the salt in the tubs has drained twelve hours, the tubs are reversed, and then withdrawn from the squares of salt, which are removed to the drying chamber, where they are allowed to remain until they become dry. From a salt-pan twenty feet square two hundred tubs of salt, each containing thirty pounds of dry salt, are removed in a day. The pans are not allowed to cool, except for purposes of cleansing, the brine being repeatedly pumped in, and the process of evaporation being continuous. About once a week the salt is more thoroughly removed than usual, and the brine in the

pan allowed to run low; the pan is then seated over the fireplace. This operation, called *dodging* or *scabbing*, is performed with a pickaxe furnished with a long handle, and having the iron flukes flattened at the ends. A man stands on the floor that runs round the pan, and by striking with the axe he loosens the incrustation, and then removes it with a rake and spade. The scab consists of a little clay and sulphate of lime, but principally of common salt which has been burnt on to the bottom of the pan. When a pan has been worked for a month, a scale will have gradually formed over the entire bottom. The whole of the salt is then removed, the fires put out, and the mother-liquors, being of little value where there is such abundance of brine, are run away. The whole underpart of the pan is then scaled with a hammer and chisel.

The brines of Worcestershire are of higher specific gravity than those of Cheshire, and contain twenty-six per cent. of salt; but the method of working does not differ in any essential particular from the description given, and, therefore, they do not require a separate notice.

The following tables, by Dr. CAMPBELL MORFIT of New York, show the constitution in one gramme of various samples of salt:—

This article would be incomplete without adverting to the saline springs of Syracuse, in the state of New York. Numbers VIII., XI., XIV., and XVIII., in the analyses by MORFIT are samples from this district. The springs of Syracuse, to which in a great measure the growth and prosperity of New York are attributable, are among the most interesting natural productions with which America is blessed. They occupy a circuit of about nine miles around the Southern extremity of the Onondaga lake. The salt is obtained from the water by the heat of the sun. The process of obtaining salt by solar evaporation is very simple. A series of wooden vats are built, twelve feet wide, six inches deep, and several rods in length. The brine is let into the first tier direct from the reservoir, and is left in repose until the dirt and other impurities have subsided. The clear supernatant liquor is then drawn off by siphons into the second tier of vats, which are lower than the first, where the sulphate of lime is deposited in beautiful crystals. The brine, thus purified, is redrawn off into the third and lowest tier of vats, where by exposure it evaporates, and the crystallization of chloride of sodium commences. At first the crystals are seen on the surface of the brine, and resemble drops of melted tallow let fall upon a surface of cold water. These particles accumulate, and precipitate themselves to the bottom of the vat in large quadrangular and hexangular crystals of the purest salt, hard, dry, and of a beautiful white color. This Onondaga solar or coarse salt is unsurpassed, it is said, in the world, and its antiseptic properties are widely known and appreciated. The rapidity of the process, and the consequent proportional crop, depends upon the heat of the weather; the process of evaporation being greatly retarded by a humid atmosphere. Sunshine is of course desirable at the salt works, and the superintendent keeps a close watch upon the weather. At the first symptoms of a shower all hands are immediately summoned to *push on the covers*, and the temporary roof, which is passed on rollers over the crystallizing brine, is ready to be removed the very instant the sun shines again.

The state of New York, through its superintendent, bores the wells, procures the supply of brine, and conducts it through logs to the salt works, which are the property of individuals. The localities are leased at a nominal rent, and for an indefinite number of years, but are only to be employed for the manufacture of salt. For the *raw material* a tax of one cent per bushel is levied on every bushel of salt produced. This amounted in 1856 to fifty-nine thousand nine hundred and forty-six dollars and forty-four cents; the expenses were fifty thousand two hundred and fifty-five dollars and sixty-five cents.

PHYSIOLOGICAL EFFECTS.—In minute quantity chloride of sodium is injurious to very few, if any plants, and to some it appears to be beneficial. Used moderately, it is on certain lands a most excellent fertilizer.

Salt serves many important and essential uses in the animal economy. It is employed, on account of its agreeable taste, by the people of all nations. It is an invariable constituent of the healthy blood. There is a deficiency of this saline constituent in cholera.

As a chemical antidote, chloride of sodium may be administered in poisoning by nitrate of silver. As an alterative and tonic, it is useful in scrofula and glandular diseases. As an astringent in hemorrhage, dysentery, and diarrhœa, it has been given in conjunction with lime or lemon juice. It is frequently employed as a dentifrice.

As an external application, salt has been employed for various purposes. A saturated solution, applied with friction, is used as a counterirritant and discutient in glandular enlargements and chronic diseases of the joints; as a stimulant, it is rubbed on the chest in fainting and asphyxia.

The inmates of every sea-side infirmary can tell a yet happy tale of the beneficence of salt breezes. They speak of lingering diseases fortunately ended; of long convalescence speedily consummated by cure. Many a life which seemed gradually ebbing away in the atmosphere of a crowded city hospital, have these briny vapors called back and fortified, and cheered

with long years of health. Salt plays here the part of a good fairy: it makes of this infirmary a kind of healing heaven for the bodily sick.

The duty on salt was repealed in 1823; but in 1815 the makers of bleaching powder were allowed to use rock salt duty free, under the inspection of the excise, who required that the salt should be crushed at the mines and mixed with a certain proportion of ground manganese, so as to render it unfit for curing purposes. The Editor's father decomposed salt which was six pounds a ton in Dublin in the year 1819. Mr. MUSPRATT mixed it with oil of vitriol, condensing the evolved hydrochloric acid in a series of stone jars. It was in Liverpool, in 1823, that he first decomposed salt in an open furnace, *disregarding entirely the hydrochloric acid*, which escaped and was diffused throughout the atmosphere. The salt he employed at first was termed *herring salt*, and cost forty shillings a ton. The price now is only eight shillings.

SULPHATE OF SODA.—GLAUBER'S SALT.—SALT CAKE.—*Sulfate de Soude*, French; *Schwefelsaures Natron*, German.—This salt was discovered by GLAUBER in 1658, and since that time has been commonly known by his name. It exists in nature in both the mineral, vegetal, and animal kingdoms. It is a very common ingredient of mineral springs of the purgative class, and is also one of the salts met with in small quantity in most terrestrial waters. Amongst the English medicinal waters, it exists in considerable quantity in those of Cheltenham, of Leamington, and of Spital.

In some springs, as in that of Paipa among the Andes, it is so abundant that crystals of it are formed upon the surface over which the water is thrown; it is likewise found in crystals in the brine springs at Salinas d'Espartinas, near Madrid. In the latter locality the sulphate exists as *Thenardite*; while in the former it is in the hydrated state, or *Mirabilite*. GMELIN accounts for its presence in mineral waters, on the supposition that it is formed by double decomposition from common salt and sulphate of magnesia contained in the liquid, thus—

Sulphate of soda in the form of mirabilite is also found in several localities in Austria, in Bohemia, in the Tyrol, and in several places in Spain and Hungary, as well as in Switzerland; on lavas, and as an efflorescence on the Siberian and Caspian steppes. A mixture of the crystallized salt with gypsum—*Glauberite*—was discovered by GIMBERNAT in the canton of Argovie in Switzerland; the same compound has been found in crystals and reniform masses, embedded in rock salt, at Villarubia in Spain, at Vic in Lorraine, Berchtolsgrad in Bavaria, and at Atacama in Chili. In the vegetal kingdom, sulphate of soda is found in the ashes of some plants which grow by the sea-shore, as the *Tamarix gallica*; and lastly, it is found in some of the animal fluids, as the blood and urine. Artificially this salt is extensively made, and its production being the first stage of the process for the conversion of common salt into carbonate of soda, it is a most important article in commerce.

It is obtained by heating common salt with sulphuric acid, and is also a by-product in the preparation of nitric acid, of sal ammoniac, of carbonate of magnesia, in the amalgamation of silver ores; and it may also be obtained from many glass slags, if native or artificial soda has been used in the preparation of the glass.

Preparation.—Sulphate of soda may be most conveniently prepared in the pure state, by causing liquid sulphuric acid to react on chloride of sodium. When the two substances are mixed, violent effervescence ensues, hydrochloric acid being evolved; the effervescence having partially subsided, heat is applied to the vessel, and continued until the whole of the hydrochloric acid is expelled, and the mass becomes dry. The following diagram shows the change that takes place:—

The dry mass obtained as above, usually contains a little sulphuric acid more than is required to produce neutral sulphate of soda. This is removed, after solution in water, by the addition of a sufficient quantity of carbonate of lime, or the excess of acid may be neutralized by the addition of carbonate of soda. The

solution is now to be filtered, evaporated, and set aside to crystallize. The crystals obtained by resolution and recrystallization yield the salt chemically pure. Or the menstruum may be obtained directly by dissolving carbonate of soda in dilute sulphuric acid.

Crystallized sulphate of soda, procured as above,

contains to each equivalent of sulphate ten equivalents of water, and consequently, is represented by the formula $\text{Na O, SO}_3, 10 \text{ HO}$. The anhydrous salt is obtained by heating the crystals to redness, or, according to FARADAY, in anhydrous crystals, by evaporating an aqueous solution at a temperature considerably below 212° . MISTCHERLICH gives the degree at 104° , and others state it to be as low as 91° .

Properties.—The primitive form of the ordinary crystallized sulphate is the oblique rhombic prism. The anhydrous salt forms in crystals belonging to the right prismatic system. This latter, which is transparent, when exposed to the air becomes opaque on the surface, owing to absorption of water. The taste of the crystallized salt is cooling and bitterish saline. By exposure to the air it effloresces, with the loss of all its water. The perfectly effloresced salt intumesces in very moist air to three times its bulk, and then becomes a crystalline mass of ordinary Glauber's salt, with a slight excess of water. When the crystallized salt is heated, it undergoes the aqueous fusion, gives off its water, and thereby becomes a white solid; but at a red heat this again becomes liquid. One part of the crystals dissolves in three parts of water at 60° ; at 212° water dissolves its own weight of the salt. It is insoluble in alcohol. A crystallized sulphate of soda is also known, containing eight equivalents of water, and having the formula $\text{Na O SO}_3, 8 \text{ HO}$.

Physiological Effects.—Sulphate of soda is a mild but efficient cooling laxative or purgative salt, promoting secretion and exhalation from the mucous membrane of the stomach and bowels without causing inflammation or fever. It was formerly the most favorite saline cathartic in this and other European countries, but since the beginning of the present century has gradually been displaced by the sulphate of magnesia.

Manufacture of Sulphate of Soda.—Sulphate of soda possesses more than a chemical interest. Its preparation, as previously mentioned, is the first stage of the

process now so extensively carried on for the conversion of common salt into carbonate of soda. In the production of the dry salt, technically known as *salt cake*, sulphuric acid is caused to act upon common salt in a proper apparatus, the products of the reaction being salt cake and hydrochloric acid. Until of late years the decomposition was effected in an ordinary reverberatory furnace, named the decomposing furnace. Some furnaces of this kind were constructed with two compartments, in one of which the materials were mixed, the greater part of the gas liberated, and the liquid evaporated to a pasty condition; in the other the calcination of the residuary sulphate was effected. In many decomposing furnaces the whole operation was carried on in the same division. An important improvement on this plan of decomposition was effected by introducing into the decomposing bed of the double furnace a lining of sheet lead, upon which the materials are mixed and brought to a pasty consistence, and they are then removed to the roasting bed to be more completely freed from acid. Furnaces of this kind are still in use in many alkali works. But for the most complete apparatus for the production of salt cake, manufacturers are indebted to Mr. JOHN LEE, who proposed the substitution of a concave iron pan for the leaden one previously employed. The advantages obtained by the use of these pans are, first, a great diminution of the expense of production, since the leaden pans rapidly become corroded during the process; and, secondly, that with the iron pan a much stronger sulphuric acid may be employed to effect the decomposition, with the further advantage of preventing the formation of so much bisulphate of soda as by the old method.

A description of the annexed woodcuts—Figs. 511 to 514—will show the most approved form of apparatus in use at the present day. Fig. 511 is a transverse section of two decomposing pans, A, A, formed of cast-iron, weighing about five tons each, and suitably set in brickwork, so as to allow the bottom and sides to be

Fig. 511.

exposed to the fire. The pans are covered with a sheet of iron, *b*, the joints made good with luting. *E* is the fireplace; and the flues, *F*, *F*, pass over and under the pans, but not through them. The roof of the pan is not always constructed of iron; a brick roof is frequently in use, the arch being higher in proportion to allow of its being self-supporting.

There are three openings into each of the pans, one through which the charge is introduced, and shown at *h*; the other immediately opposite, through which the charge is pushed out, seen at *k*, in Fig. 512; the

third is for the escape of the acid vapors through the pipe, *c c*. This pipe is composed of short lengths of closed earthenware fitting into one another, and well luted to prevent escape of gas.

Two of these pans are usually worked together, and the hydrochloric acid gas brought into one main flue, as shown in the figure. The salt cake furnace is attached to the decomposing pan, as shown in Fig. 512. The sole of this furnace, which is flat, is constructed of good fire-brick or Welsh tiles, and the roof, which is only slightly arched, is of fire-brick. *h* is the fireplace,

and *F F* are the flues passing over and under the furnace, but not through it. *G* and *E* are openings for the purpose of turning over and withdrawing the charge. *C* is the tube through which the acid gas escapes.

Fig. 512.

The charge is pushed into the furnace from the decomposing pan through *K*.

Fig. 513 shows a plan of the decomposing pans and furnaces. *A A'* are the decomposing pans; *C C'*, the acid flues; *F F'*, and the dotted lines, *fff*, show the arrangement of smoke flues.

Fig. 513.

charge of salt, amounting to about sixteen hundred-weight, is introduced through the doorway, *H*. The tile which closes this is now fitted into its place, and the sul-

Fig. 514 is a transverse section of the same through *P, F, Q*, in which the arrangement of flues is plainly seen.

The following is the method of producing salt cake with the use of the apparatus described. The pan, *A*, is first heated to a suitable temperature, and the

phuric acid is run in. It is preferred to use acid of about specific gravity, 1.450, and heated to a temperature of about 120°, so as not to cool the pan more than is neces-

sary. The proportion of acid required is about one thousand eight hundred pounds, or one hundred and

twenty-three and a half gallons, that being the quantity which, making allowance for water and slight impurities

Fig. 514.

in the salt, is just sufficient to convert all the chloride of sodium into sulphate of soda; and the charge is usually measured out by filling a small leaden vessel, of known capacity, placed near or over the decomposing pan, so as to allow of the acid being run in upon the salt by a siphon. The acid and salt having both been introduced, the tile closing the opening, *H*, is now removed, and the materials thoroughly mixed with an iron rake. This mixing serves at the same time to prevent frothing, by facilitating the escape of gas. The doorway is then effectually closed with the tile and proper luting, and the fire urged under the pan. In the course of an hour nearly all the acid vapor will have been disengaged, and the greater portion of the common salt be converted into sulphate of soda. Much of the sulphuric acid, however, is now found combined with soda as bisulphate of soda; and to decompose this, so as to render the excess of acid serviceable in forming sulphate of soda with the undecomposed common salt, a high temperature is required, to obtain which the charge is now pushed forward through the opening, *K*, into the salt cake furnace, *D D'*—Fig. 512—by means of rakes inserted through *H*. The charge is spread evenly over the floor of the furnace, the tools being worked through the doorways, *E* and *G*. The salts are here exposed to a low red heat for about one hour, and frequently turned over during this interval. Meanwhile the decomposing pan having remained empty for a time, to enable the workman to raise the temperature to the proper extent, a new charge of common salt and acid is introduced, and worked off in the manner described.

The sulphate of soda is heated in the salt cake furnace until it assumes a reddish-yellow tint, when it is raked out through the doorway, *G*, and is considered finished.

From two furnaces, such as shown in the drawings, and of the dimensions given, ten charges each may be drawn in a day, or sixteen tons of common salt may be decomposed, with the production of nearly nineteen tons of salt cake. The working of sulphate of soda is effected, however, under different arrangements, in a manner even more rapid than this. Thus, when an open reverberatory furnace is used in place of the closed furnace described, sixteen charges a day may be drawn; the open furnace being capable of more rapid heating than the *blind* or *closed* furnace described, and the acid gases being more readily carried away by the current of air passing over the heated salt.

Condensation of the Hydrochloric Acid.—It now remains to consider the various plans adopted to effect the condensation of the hydrochloric acid gas evolved from the mixture of acid and salt. The whole or nearly the whole of this was, in the early days of the manufacture, allowed to escape into the air, the inconvenience attending its condensation having been considered of greater consequence than the value of the liquid acid. But owing to the great demand for bleaching powder, the manufacturer found it would be to his interest to condense *the whole* of the acid, so as to use it in the preparation of bleaching agents.

The plan of apparatus at present employed for effecting the condensation of gaseous hydrochloric acid to the liquid form, was first suggested and patented in 1836 by Mr. GOSSAGE; the condensers have, however, been greatly improved since that period. The gas, as evolved from the mixture of sulphuric acid and salt, is conducted by means of pipes inserted in the brickwork of the dome of the pot, and in the arch of the furnace, to a massive tower or series of towers—Fig. 515—constructed of large rectangular slabs of silicious stone, cemented together and bound exteriorly by stout iron clamps. These towers may be filled with small pebbles or rounded flints, but usually coke is preferred, and a stream of water is allowed to flow from a cistern on the top slowly through the mass; this, meeting with the ascending gas, completely condenses it, and ultimately flows out by an aperture in the bottom to a recipient. The mode of condensing adopted previously to the introduction of these towers was, as previously stated, by a series of WOLFFE'S bottles; a system far too cumbersome to be adopted successfully on the very extensive scale on which the manufacture is now carried on.

A connection exists between the first and second towers near the summit, and from the base of the second tower an underground flue, for the purpose of creating a draught through the apparatus, is carried to the chimney-stalk. The gases eliminated from the mixture of salt and sulphuric acid enter the first tower at its base, and pass upwards through the moistened coke; whatever is uncondensed is carried into the second tower, and in its passage through this downwards the whole of the acid is removed; and the uncondensable gases pass by the flue to the chimney.

If the towers are of sufficient height, two only will be requisite to effect complete condensation of the acid; but if this should not be the case, three or more may be connected together; the first two at the summit,

the second and third at the base; the third with the fourth at the top, and so on through the series. By this arrangement acid may be obtained of specific

gravity 1·150 to 1·160, quite strong enough for the decomposition of binoxide of manganese.

If the hydrochloric acid be required for other pur-

Fig. 515.

poses than the decomposition of binoxide of manganese, as for the evolution of carbonic acid from chalk or limestone, condensers of a still more simple nature may be employed; because then, a weaker acid answering the purpose equally well with a strong one, a far greater proportion of water may be used. In this case, a single tower divided into two compartments by a partition wall, and the whole well filled with small pieces of coke and supplied with water in sufficient quantity, will effect the condensation of the whole of the acid evolved. But unless the acid can be at once consumed on the spot, it is of course always desirable to obtain it in as concentrated a condition as possible. In some manufactories, as well to prevent the escape of hydrochloric acid as for economy, the towers, constructed as above described, are filled with limestone instead of coke or pebbles; and the carbonic acid evolved is applied in the preparation of bicarbonate

of soda, as will be hereafter mentioned. It has also been proposed to avoid the evolution of hydrochloric acid altogether, by adding sulphuric acid and zinc to a solution of chloride of sodium. In this case, hydrogen is eliminated, and there is produced chloride of zinc and sulphate of soda as in the annexed equation:—

The products can be separated by crystallization; and from the mother-liquor, lime will precipitate hydrate of zinc, which can afterwards be substituted for metallic zinc, for the production of sulphate of soda from common salt.

Various other processes for the preparation of salt-

cake have been adopted on a more or less extensive scale. In some of these, hydrochloric acid is also obtained; in others chlorine, or a mixture of this and hydrochloric acid; and in others, the chlorine is removed in combination with bases. One of the oldest of these methods consists in heating together in a reverberatory furnace a mixture of common salt and pyrites—bisulphide of iron. In this process, the sulphur of the bisulphide becomes oxidised to sulphuric acid, under the influence of heat, atmospheric air, and of sodium; and the sodium being at the same time converted into soda, combines with the acid produced. The chlorine of the common salt partly combines with the iron, and the other portion unites with the hydrogen of the water or steam evolved from the combustible materials employed to form hydrochloric acid. The heat being continued, the chloride of iron at first formed becomes decomposed; nearly pure chlorine is evolved, and sesquioxide of iron remains in admixture with the sulphate of soda. By lixiviating the mass with water, the sulphate of soda is dissolved; and by evaporating the solution, the pure salt may be obtained in crystals, or as an anhydrous mass. Mr. LONGMAID, some years ago, proposed this method for the preparation of sulphate of soda for the alkali manufacturer, and at the same time of pure chlorine for the production of bleaching powder. He suggested that the chlorine might be freed from hydrochloric acid by bringing it in contact with a surface of wood, kept moist from the outside; and the gas from it, if to be used in the production of bleaching powder, must then be dried by any convenient method. The mixture of sulphate of soda and oxide of iron he directs to be employed, instead of the pure sulphate, in the preparation of black ash according to the usual process.

This plan is not likely to supersede the old method of manufacture; for, besides the great defect arising from the slowness with which the decomposition of the common salt proceeds, there is, according to DUMAS, a considerable loss of sulphur during the process, owing to the incomplete oxidation of this element. This portion of sulphur is evolved as sulphurous acid in admixture with hydrochloric acid.

Protosulphate of iron has been used to a considerable extent for the conversion of chloride of sodium into sulphate of soda. This may be effected in two ways; firstly, by dissolving the copperas and salt together in water, when a double decomposition takes place, with formation of sulphate of soda and protochloride of iron as in the annexed equation:—

The sulphate of soda may be procured in hydrated crystals— $\text{Na O SO}_3, 10 \text{ HO}$ —by exposing the solution to a low temperature; or, in an anhydrous state as an opaque precipitate, by concentrating the solution at the boiling point. In either case the chloride of iron remains in the mother-liquor.

The other process for the conversion of chloride of sodium into sulphate of soda, by means of sulphate of iron, consists in the calcination at a red heat, in a reverberatory furnace, of an intimate mixture of the

two salts in the proportion of sixty parts of chloride of sodium to one hundred and forty of the iron salt. In this case, there is formed, at first, sulphate of soda and chloride of iron as above. By heat, however, the chloride is transformed, by virtue of the decomposition of water, into hydrochloric acid, which is disengaged, and into oxide of iron, which remains mixed with the sulphate of soda. There is also eliminated a little sulphuric acid and chlorine. DUMAS states that the process may be rendered more productive of sulphate of soda, by mixing the two substances together in powder, and leaving the mixture for some days in a heap moistened with water, and afterwards heating to redness. This mode of manufacture of sulphate of soda is employed in the North of France.

Among the processes for the manufacture of caustic soda, that of Mr. WILLIAM HUNT has been mentioned. It consists in the decomposition of sulphide of sodium by means of oxide of zinc or of copper, when there are produced caustic soda and sulphide of copper or zinc. The metallic sulphide thus obtained, he directs to be applied in the preparation of sulphate of soda, either by roasting so as to produce sulphuric acid in the ordinary manner, and causing this to act upon common salt; or by heating the sulphide to a temperature of about 400° , with exposure to the air, whereby the sulphide is converted into sulphate. The sulphate of copper or zinc thus obtained, after having been freed from the accompanying oxide or unaltered sulphide by lixiviation with water, is mixed with a solution of common salt, when there are produced sulphate of soda and chloride of zinc or of copper. The alkaline sulphate is separated from the metallic chloride by crystallization, and from the chloride remaining in the mother-liquor, oxides of zinc or of copper, in a condition to be used for the decomposition of more alkaline sulphide, is obtained by the addition to the solution of milk of lime.

The preparation of sulphate of soda and of chlorine for bleaching powder was carried on simultaneously at former periods. The process which was first adopted by the Messrs. TENNANT and Company of Glasgow, consists in heating together a mixture of chloride of sodium, binocide of manganese, and sulphuric acid in leaden vessels, when changes ensue, as represented in the subjoined equation:—

The whole of the chlorine of the common salt is therefore evolved in the pure state, while there remains a mixture of sulphate of soda, sulphate of manganese, and the excess of sulphuric acid employed. To this as much common salt is added as is necessary to saturate the free sulphuric acid, and the whole is heated in a reverberatory furnace. In this operation, the manganese and iron-salts are decomposed; and the sulphate of soda may then be withdrawn from the fused mass with water. It will be observed that in this process one half of the sulphuric acid employed is lost; and this

being of greater value than the equivalent proportion of hydrochloric acid lost in the other methods of treatment, the plan has been generally abandoned.

Besides these sources of sulphate of soda, it is obtained also frequently from the mother liquors of common salt. When these solutions are sufficiently concentrated, a substance separates in flakes, which is a double salt composed of sulphate of soda and sulphate of lime. This is collected, washed with cold water to remove adhering chloride of sodium, and then treated with boiling water. The sulphate of soda now dissolves; and the solution, after being allowed to deposit, is decanted and evaporated to the crystallizing point or to dryness. The sulphate of soda in these liquors is probably formed by double decomposition of sulphate of magnesia and chloride of sodium.

Crude salt cake, prepared by the action of sulphuric acid upon common salt, usually contains from ninety-two to ninety-six per cent. of sulphate of soda, and, besides free sulphuric acid, chloride of sodium, minute quantities of other matters, as sesquioxide of iron, *et cetera*. A sample prepared at the works of JAMES MUSPRATT and Sons, Liverpool, was examined in the Editor's laboratory, and gave the following results:—

Sulphate of soda,	96.515
Sulphate of lime,	0.923
Sulphuric acid,	0.616
Chloride of sodium,	1.345
Sesquioxide of iron,	0.191
Water,	0.187
Insoluble matter, coal, <i>et cetera</i> ,	0.130
Loss,	0.093
	100.000

NITRATE OF SODA—CUBIC NITRE—SODA-SALT-PETRE.—*Nitrate de soude*, French; *Salpetersaures Natron*, German.—Nitrate of soda may be prepared artificially by saturating nitric acid with carbonate of soda, and evaporating the solution to dryness; by precipitating nitrate of baryta or of lime with sulphate of soda, allowing the solution to deposit the insoluble earthy sulphate, decanting the clear liquor, evaporating and allowing the nitrate to crystallize; and lastly by mixing solutions of nitrate of potassa and of sulphate of soda, when double decomposition succeeds, producing sulphate of potassa and nitrate of soda. The latter salt, being much the more soluble of the two, remains in the liquid after the former has crystallized, and may be obtained as already directed. The pure salt may likewise be obtained from the common variety, by dissolving the latter in the least quantity of boiling water, filtering the liquid whilst hot, and stirring the filtrate till quite cold. The crystalline deposit which forms during the last operation is transferred to a funnel loosely plugged with cotton, allowed to drain, and then washed by pouring on it cold water in small portions at a time, allowing each washing to drain off thoroughly before the succeeding edulcoration, and continuing the operation till the washings give no milkiness with nitrate of silver. The powder is then dried.

Properties.—Nitrate of soda crystallizes in transparent rhombohedral prisms; it has a cooling and bitter taste. Water dissolves it with great reduction of temperature; three parts at 60°, one part at 125°,

and much less than its own weight at 212°, are required to dissolve one part of the salt. It becomes damp only in moist air; but, according to some chemists, deliquesces perfectly in an atmosphere saturated with watery vapor. When heated, it melts and evolves at first pure oxygen gas; afterwards the oxygen becomes mixed with nitrogen, and fumes of nitrous acid. It detonates with charcoal and other combustible bodies, but less violently than the corresponding salt of potassa. It is composed centesimally of—

	At. weight.	Centesimally.
1 Eq. of soda,	31	36.47
1 Eq. of nitric acid,	54	63.53
	85	100.00

Its chemical symbol is Na O, NO₅.

COMMERCIAL NITRATE OF SODA.—*Sources.*—This compound is not a manufactured product, but is found associated with other saline bodies distributed over various parts of the earth in the form of a mineral deposit, or as an efflorescence on the surface of the ground. Associated with nitrate of potassa, it is met with in Spain and in various parts of India; but the most remarkable deposit of this salt occurs in Peru, where a tract of country one league long and several broad, in all comprising, perhaps, fifty square leagues, is more or less incrustated with that substance. The existence of this salt in Peru has been known for about a century, and in 1820 some of it was sent to England; but the duty imposed was so high that it was not brought into the country. Between 1820 and 1830 several attempts were made to induce manufacturers to use the salt in England, America, and France; but it was not until 1831, that its real value as an article of commerce became generally known.

On the coast of Peru the land rises in a very precipitous manner to the height of about four thousand feet above sea-level; at this height the rocks shelve down a little into the country, and the view opens out on a plain of immense extent, varied only by slight undulations of the surface. These grounds, called the Pampas, are dry, arid plains, on which hardly a trace of vegetation is seen; plants of the cactus family even scarcely being able to maintain a struggling existence. No rain falls on these plains; and the deep blue of the sky or the bright glare of the sun is never obscured by a cloud; even the phenomenon of wind is hardly known; and the character of the locality is that of stillness, so profound indeed as to impress itself upon both man and beast.

From thirty to thirty-five miles from the coast, just before reaching the level ground of the Pampas, are found the deposits of nitrate of soda most esteemed for their purity and most easily procurable from their thickness. The depth of the layers varies from a few inches on the level plains to four, and even seven feet, on the slopes and hollows of the ground. The salt is found on the surface of the ground, or covered only to a very slight extent with a hard crust, consisting of a mixture of common salt and clay. This crust increases in thickness in some parts to four or five feet; and the crude nitrate or *nitrate calèche*, as

it is termed, under the thick layers, is the material most sought after for its purity. The workable nitrate—being that found of sufficient thickness—occurs in patches of about five hundred yards, mean breadth; and the character and value of the deposit varies considerably even within the limit of a few hundred yards. From an examination of several samples, the crude material has been found to contain on an average from twenty-five to thirty per cent. of impurity; this consisting principally of common salt, but associated with small quantities of chloride of iron, sulphate of soda, sulphate of lime, and iodide of sodium, and in some specimens clay.

Purification.—It has already been observed that the purest layers of nitrate lie under a hard crust of earthy matter, mixed with chloride of sodium; this is so hard that it is usual to employ the aid of gunpowder in dislodging the material by blasting. The powder used for this purpose is a coarse material made on the spot from the nitrate of soda, charcoal, and sulphur; the charge, where the vein of salt and the covering is thick, will frequently be three hundredweight, and this will dislodge upwards of twenty tons of salt. The pieces thrown up are broken with hammers, and a selection is made of the purest specimens. The crude product obtained in the manner described is, however, very seldom found in such a condition of purity as to be capable of immediate application in the arts; and the great difficulty of getting the salt from the *officinas* or *burks* to the coast, renders it imperative to purify the substance as much as possible in the localities that yield it. The process of purification usually adopted is, however, extremely simple, and is dependent on the difference in solubility between common salt—which is the principal foreign substance—and the nitrate of soda, at temperatures above the common.

The apparatus employed for this purpose consists of two dissolving vessels, a settling pan, and several crystallizing pans. The dissolving vessels are hemispherical pans of cast-iron, about six or seven feet diameter and three or four feet deep. They are dead-set in brick-work, and one fire plays round and between them. Into these vessels a quantity of mother-liquor, saturated with common salt from a preceding operation, is run, and a charge of nitrate calèche, consisting of fifteen quintals, is now thrown in, and the whole boiled for four or five hours, until the liquid is considered to be saturated with nitrate of soda. The solution is now ladled by hand into a settling pan, in which the liquid clarifies by subsidence. In a few hours the clear lie, still hot, is drawn off into shallow coolers, constructed of boiler-plate iron, and in these the nitrate of soda crystallizes out as the liquor cools. The crystals are shovelled out on to the ground, and dried by exposure to the sun, while the mother-liquor is made available for the solution of a further quantity of the crude material. The ordinary yield of crystals from fifteen quintals of nitrate calèche, is from eight to ten quintals, or about seven and a half hundredweight. A quantity of these dry crystals, sufficient for a load, is now introduced into two bags; these are slung on the back of a mule, and with this load the animal winds down the sides of the mountain to the sea-coast. The

mother-liquors, after being used for several operations, become charged to a considerable extent with iodide of sodium, when that substance is a constituent of the crude material, but little iodine is obtained from this source, although, with proper management and utensils, the working might be made a profitable investment. The use of steam has been tried in purifying the crude nitrate, but with only partial success. The apparatus employed for this purpose consists in an iron vessel constructed in the form of an inverted cone, both ends being open. This vessel is filled with nitrate calèche and steam blown in through the bottom of the cone. The great solubility of the nitrate of soda in water, and its powerful attraction for that substance, induces its separation from the common salt, and a saturated solution of nitrate of soda, made by the condensed steam, flows out through the bottom of the cone. But owing to the necessity for introducing the crude material in lumps, a great portion of the soluble part in the interior of these is protected by the undissolved portion on the outside from contact with the steam, and as a consequence, a large amount of nitrate of soda is left undissolved; the loss from this source is the cause that little favor has been extended to the process.

One of the greatest sources of inconvenience in the purification and export of nitrate of soda is the want of pure water all along the sea-coast. On the Pampas a brackish water is obtained by boring for a few yards, and this, although not agreeable, is yet drinkable; but at Iquique, which is the port whence almost all the nitrate of soda is shipped, no drinkable water is to be found; the whole supply being derived from the distillation of sea-water. There are two large distilleries established to supply the want in this respect. The water obtained is, however, too expensive an article to be used in quantities sufficient for the healthy sustenance of animal life, and the mules employed in bringing down the nitrate of soda to the port, obtain a supply only by bringing it down with them from the mountains. Their privations in this respect, and the consequent injury to healthy life, is one of the greatest obstacles to the cheap supply of nitrate of soda.

This salt, obtained by the method described, is now usually supplied in commerce in a condition of great purity; the foreign matters, including water, or the *refraction*, as these are collectively termed in commercial circles, seldom exceeding seven per cent., and being more generally below six per cent. The impurities consist principally of common salt and water, the latter being attracted from the atmosphere; but a small proportion of sulphate of soda and lime is also found in it, with variable quantities of sand. No other substance can be detected in the commercial article in sufficient quantity to influence its value; but the actual value of the salt is so high that it becomes a matter of importance to detect the proportion of impurities, however small in amount. The following rapid and effectual method of doing so is recommended for those who are unacquainted with the more delicate manipulations of analytical chemistry:—A small quantity of the sample—say one hundred grains—is weighed out, and dried in a water or oil bath until it no longer loses

weight. The difference will give the amount of water. Another quantity, about one hundred grains, is weighed out and dissolved in pure distilled water, a few drops of pure nitric acid added, and the liquid made up to a thousand grain measures with water. About a hundred grain measures of this solution are transferred to a glass tube, and tested by comparison with several dilute standard solutions of common salt, contained in similar tubes, by means of a solution of nitrate of silver. The amount of cloudiness in the precipitate is observed with great nicety, and by comparison with the precipitate observed in the standard solutions of common salt, the per centage of this substance in the sample tested may be ascertained with much exactness. A very important point to be observed in this method of testing, is to have the solutions so dilute that only a distinct cloudiness shall be produced by the addition of the silver salt. By attention to this matter very minute differences are readily observed.

The per centage of sulphate of soda is determined by a similar method, using hydrochloric acid to acidify the solution of the sample in place of nitric acid, and employing dilute standard solutions of sulphate of soda, to compare with the sample. The precipitation is effected with a few drops of a strong solution of chloride of barium; but while the indications of chloride of sodium afforded by a silver salt are immediate, the cloudiness produced by adding chloride of barium to sulphate of soda, contained in a large quantity of solution of nitrate of soda acidified, is not immediately perceptible to its full extent when the solutions are weak. It is therefore advisable to compare the results obtained with the standard solutions, and the sample tested, only after the lapse of some hours. With this simple precaution the estimation of the per centage of sulphate of soda is effected with great accuracy by the method described.

The sand is estimated by dissolving the salt in water, filtering the solution, and after thoroughly washing the filter paper, calcining the insoluble portion. The per centage of water, chloride of sodium, sulphate of soda, and sand, being subtracted from one hundred parts of the commercial sample, will give the per centage of pure nitrate of soda to a very close approximation.

Various methods of estimating the amount of nitrate by a direct process are practised; but accurate results are only obtainable by the exercise of considerable skill in analysis. These are described under the article, NITRATE OF POTASSA, page 735; and the same description will apply equally well to the estimation of nitrate of soda, with the simple alteration of the equivalent weight of the former to that of the soda salt; that is, by putting the equivalent weight of nitrate of soda—85—in place of 101, the equivalent of nitrate of potassa.

Nitrate of soda is distinguished from potassa-nitre by its deliquescent property, a character that renders it quite inapplicable to some of the purposes for which the latter is employed, as for instance to the manufacture of gunpowder. It is extensively employed in the manufacture of nitric acid, owing to its cheapness, and also because it affords nearly ten per cent. more nitric acid than the corresponding potassa salt. Its

principal consumption is in the production of nitric acid, and as a vehicle for conveying oxygen to the sulphurous acid of vitriol works, whereby it is converted into sulphuric acid. Of late years it has been used largely as a manure. The subjoined are analyses of the commercial salt; but besides the ingredients named, LEMBERT found also small quantities of iodide of sodium and iodate of soda:—

	Hoffstetter.	Lecanu.	Wittstein.

PHOSPHATE OF SODA.—This salt has long been known as one of the constituents of urine, having been discovered in that fluid by HELLOT in 1737. It was not, however, sufficiently distinguished from other salts till a much later period, when it was examined and analysed by PROUST, ROUELL, and KLAPROTH.

It is most conveniently prepared by adding carbonate of soda to the solution of acid phosphate of lime, obtained by treating bone earth with sulphuric acid. The liquor should be maintained at a boiling temperature; and the carbonate of soda must be added as long as effervescence continues, or until the solution has an alkaline reaction. The effervescence is due to the escape of carbonic acid; the soda unites with the free phosphoric acid and with a portion of the acid of the superphosphate, while at the same time phosphate of lime, or a mixture of this and carbonate of lime, is precipitated. This insoluble matter is removed by filtration, and the liquor is then boiled down and allowed to crystallize. To obtain an additional quantity of the salt from the mother-liquors, it is necessary first to examine if these manifest an acid or an alkaline reaction. In the first case, more carbonate of soda must be added to restore the alkaline reaction, and the liquor again evaporated and set aside to crystallize.

If, on the contrary, too much carbonate of soda has been added originally, the crystals obtained will require to be washed, a fresh portion of the acid phosphate of lime added, the solution evaporated, and again allowed

to crystallize. To obtain good crystals of this salt, it is necessary that a slight excess of carbonate of soda be present. In operations on the large scale, when it may be advisable to economize the phosphate of lime, FUNCKE directs that the precipitate obtained on adding carbonate of soda be dissolved in nitric acid; sulphate of soda is then added, and the nitric acid is removed by distillation. The residue is then treated with water, when a solution of phosphate of soda is obtained, with a deposition of sulphate of lime.

Properties.—Phosphate of soda crystallizes in beautiful transparent colorless rhombohedral prisms terminated by four converging planes. The crystals are represented by the formula, $2 \text{Na O, HO, PO}_5, 24 \text{HO}$. Their taste is cooling and mildly saline, not unlike common salt. They are soluble in four parts of water at 60° , and in two of boiling water. Exposed to the air, the salt undergoes efflorescence, but this takes place only at the surface; beneath, the form and transparency are preserved. Heated, the crystals fuse in their water of crystallization, and then water passes off. But one equivalent of water for every two equivalents of soda is obstinately retained, and cannot be expelled, except at a red heat. When two equivalents are driven off, the salt acquires peculiar properties, different from those it originally possessed, being converted into pyrophosphate of soda. The cause of the change of property, according to GRAHAM, is that in the common or rhombic phosphate, the acid is united in the proportion of one equivalent with two of soda, and one of water in the capacity of a base, constituting a tribasic phosphate of soda and water; and that when the basic water is expelled by a red heat, the salt becomes a bibasic phosphate, composed of one equivalent of acid and two of soda, and, therefore, a totally different compound. Phosphate of soda, consisting of two equivalents of soda, one of acid, and twenty-five of water— $2 \text{Na O, HO, PO}_5, 24 \text{HO}$ —contains—

	Centesimally.	
Soda,	62.6	40.00
Phosphoric acid,	71.4	45.62
Water,	22.5	14.38
	156.5	100.00

The uses of phosphate of soda are principally in medicine, and in the laboratory of the chemist.

Physiological Effects.—This salt is an excellent saline cathartic, equal to the most esteemed of the neutral salts in this respect, and superior to them in the mildness of its taste. As a purgative, it is employed in the diseases of children and delicate persons in preference to other saline substances, on account of its slight taste and mild action. It is well adapted for febrile and inflammatory disorders. It is one of the substances which have been applied in cholera, to restore to the blood its deficient saline matters. On account of the phosphoric acid which it contains, it has been supposed to be especially applicable in those diseases in which there is a deficiency of phosphate of lime in the bones. It has also been administered in diabetes.—*Pereira*.

Ordinary phosphate of soda—the variety above described, is known in combination with one equi-

valent only of water, the salt having this formula, 2Na O, HO, PO_5 ; and also with fifteen equivalents of water, represented by $2 \text{Na O, HO, PO}_5, 14 \text{HO}$.

Pyrophosphate of Soda— 2Na O, PO_5 —obtained by heating the simple phosphate, has already been mentioned. This is also known in combination with water, the crystallized salt being $2 \text{Na O, PO}_5, 10 \text{HO}$. **Metaphosphate of Soda**— Na O, PO_5 —is obtained by heating the pyrophosphate, and according to the degree of heat used in its formation, appears in three different forms which, though the same in composition, possess different properties, as if the pyrophosphoric acid passed by a gradual transition into metaphosphoric acid.

Phosphate of Soda and Ammonia, or Microcosmic Salt, is a compound much used in the chemical laboratory in blowpipe examinations. It is prepared by dissolving six parts of common phosphate of soda, and one part of chloride of ammonium, by boiling with two parts of water. As the solution cools the double phosphate separates in crystals, and by a second crystallization is freed from adhering chloride of sodium. In this salt one equivalent of soda in the common phosphate is replaced by ammonia, and the crystallized salt has the composition, $\text{Na O, NH}_4 \text{O, HO, PO}_5, \frac{1}{2} 8 \text{HO}$.

When subjected to the action of heat the ammonia escapes with the water of crystallization, and a compound of similar composition to borax remains, that is to say, a compound which contains both a free acid and a readily fusible salt. It is preferred in some cases to borax as a solvent or flux in blowpipe operations, the beads which it forms with many substances being more beautifully and distinctly colored than those of borax.

BORATES OF SODA.—There are several combinations of boracic acid and soda, such as the monoborate, baborate, and quadraborate of the alkali; but the most important of them is the baborate, a salt which has been already described fully in Vol. I., page 346, *et sequitur*. Allusion may, however, be made here to another source whence boracic acid and baborate of soda may be made. This is the baborate of lime—boracite—which has been discovered in large quantities on the Western coast of America, and called after its discoverer, HAYES, *Hayessine*. It is met with in the Peruvian province of Tarapaca, near the port of Iquique, and in the same locality as that which produces the nitrate of soda in such abundance. It is imported in moderately large quantities into Liverpool. It is in the form of fibroid lumps, which, when broken, appear in loose fibres or scales of a nacreous white color, intermixed or incrustated with crystals of carbonate of lime and finely divided white clay. Baborate of soda may be prepared from this mineral by reducing it to an impalpable powder, and dissolving in ordinary hydrochloric acid, filtering or clarifying the solution by subsidence, and adding carbonate of soda to the menstruum. The lime is separated by this process as carbonate, whilst baborate of soda is produced, and may be obtained from the filtrate or supernatant liquid by evaporation, *et cetera*.

CARBONATE OF SODA.—This important salt is met with in nature under various conditions, but never in a state of purity. It exists in the soda lakes of Egypt and

Hungary, and in other mineral waters, though not in sufficient quantities to remunerate for its extraction. KUHLMANN and VOGEL found it in admixture with the sulphate of the same base in an efflorescence on the walls in several towns, and considered its production to be owing partly to the presence of soda salts in the limestone used in the preparation of the mortar, and partly to the soda in the coal with which the limestone had been burned. In plants growing on the sea-shore oxalate of soda exists, and when these are burned, the oxalate, losing carbonic oxide, becomes carbonate.

Preparation.—In a state of purity, carbonate of soda is most conveniently prepared from the bicarbonate. To obtain it, the latter salt is washed with cold water until the filtrate, after being acidified with nitric acid, is not rendered turbid by chloride of barium or nitrate of silver. The washed salt is then dried, and by gentle ignition one half of the carbonic acid is expelled, and the pure neutral carbonate remains.

The bicarbonate of soda used should be as pure as can be obtained, and must, of course, be completely soluble in water. That most suitable is obtained by passing carbonic acid into a strong aqueous solution of crystallized carbonate of soda.

The process recommended by GAY-LUSSAC, for the preparation of pure carbonate of soda, is also a good one, and less troublesome than the former. He washes the ordinary commercial crystals of this salt with cold water; dissolves them in hot water, and cools the solution rapidly by surrounding it with cold water, stirring it all the time with a spatula, so that small crystals may be formed. These are to be collected on a funnel, and after the mother-liquor has been drained off, washed with cold water till the drainings mixed with excess of nitric acid no longer give a precipitate with nitrate of silver. The crystals are then to be dried, and when heated to low redness, the pure anhydrous carbonate remains.

Properties.—Anhydrous carbonate of soda is white, translucent, of specific gravity 2.4649; it is very soluble, and much more so in hot than in cold water; its reaction is alkaline, and its taste slightly caustic, much less so than the corresponding salt of potassa.

The annexed table shows the amount of the anhydrous salt contained in *solutions of different gravities at a temperature of 59°*:—

Specific gravity.	Per cent.	Specific gravity.	Per cent.
1.1816	14.880	1.0847	7.440

Carbonate of soda forms several crystalline com-

binations with water. When a saturated aqueous solution is evaporated at a boiling temperature, small crystals are deposited containing an equivalent of water, and consequently represented by the formula, $\text{Na O, CO}_2 + \text{HO}$. Monohydrated crystals are also formed when the ordinary commercial crystallized carbonate is kept in solution for some time in its own water of crystallization, or evaporated between 167° and 190; and when commercial crystals are exposed to the air at a temperature of 100°, the monohydrated carbonate remains as an effloresced mass. The form of the crystals is that of a four-sided table. It does not melt when heated, but at a temperature from 188° to 212° loses the whole of its water. Exposed to the air, it gradually absorbs moisture, to the amount of six or seven equivalents.

When ordinary crystallized carbonate is exposed to the air at a temperature of 54°, an effloresced salt remains, containing five equivalents of water, $= \text{Na O, CO}_2 + 5 \text{HO}$. This may also be obtained in crystals by melting the same salt and maintaining it at a temperature of 92°. PERSOZ states that crystals having this composition were accidentally obtained at the Buxweiler soda works, in transparent rhombic octohedrons, which effloresced slightly in the air, and when dissolved in water, and evaporated at 86°, again yielded the same salt. According to MITSCHERLICH, a solution of protosulphide of sodium exposed to the air, and frequently also a mixed aqueous solution of chloride of sodium and carbonate of potassa, yield crystals containing six equivalents of water, $\text{Na O, CO}_2, 6 \text{HO}$.

Crystals of carbonate of soda have also been obtained containing eight equivalents of water, $\text{Na O, CO}_2, 8 \text{HO}$, in the form of rectangular prisms, terminated by four-sided summits. These are produced when the ordinary crystallized salt cools from a state of fusion, or from a saturated aqueous solution at a particular temperature.

Common commercial crystallized carbonate of soda contains a still greater proportion of water than the salt last named. These crystals are a combination of one equivalent of carbonate of soda with ten equivalents of water, and are consequently represented by the formula $\text{Na O, CO}_2, 10 \text{HO}$. They are formed from a moderately concentrated solution, at a temperature below 92°. Their crystalline form is that of the oblique prism.

When gently heated this salt fuses, monohydrated carbonate crystallizes out, and the residual liquid, although containing more than ten equivalents of water to each equivalent of carbonate, solidifies at about 92°. When exposed to the air it loses a portion of its water, and becomes covered with an efflorescence containing eight equivalents of water.

NATIVE SODAS.—In France, Spain, and other countries where common salt is scarce, or where the duty upon this article is so great as to prevent its conversion into carbonate of soda, plants and alkaline waters are extensively consumed for the soda they contain. Besides these two great sources, carbonate of soda also occurs mineralized in some countries, though not in any great quantity, and is generally the residue of the evaporation of alkaline waters.

In Egypt, in the desert of Thiaït, to the West of the Delta, there is a pit four leagues long and a quarter of a league wide, which, during the winter months, becomes filled to the height of five or six feet with violet-colored water. In the summer this water evaporates, and an incrustation of carbonate of soda remains, half an inch in thickness. At Shegedin, in Little Cur- nania, a province of Hungary, WERNER found carbonate of soda as an efflorescence on the ground, and some years ago it was extensively collected and purified. The commercial demands for soda were supplied formerly, principally by the combustion of marine vegetals. These contain the soda, according to DUMAS, as oxalate, and by calcination this is converted into carbonate of soda. The plants, after being dried in the air, are burnt in rude furnaces, at a temperature just sufficient to cause the ashes to enter into a state of semifusion, so as to concrete on cooling into moderately compact cellular masses. The substance so obtained is known under various names, according to the country whence procured, and the kind of plant consumed for its production. Among these may be mentioned the *barilla*

of Spain, *kelp* of Scotland, *varec* of Brittany and Normandy, *blanquette* of Frontignan and Aiguemorte, and the *salicor* of Narbonne. The soluble portion of these ashes consists of carbonate, sulphate, and hyposulphate of soda, sulphide, iodide, bromide, chloride, and ferrocyanide of sodium, and sometimes also the corresponding compounds of potassium; and the matters insoluble in water are carbonate and phosphate of lime, sulphide of calcium, magnesia, alumina, silica, sulphide of iron, and charcoal. Of the several varieties, *barilla*, known also in commerce as Alicante soda, Carthagenia soda, and Malaga soda, is by far the most valuable. It contains from fourteen to twenty per cent. of soda in the state of carbonate. It has a greyish-blue color, and when exposed to the air for some time effloresces at the surface. It is hard and difficult to pulverize, and has a pungent alkaline taste. The plant yielding this ash is the *salsola soda*; it is carefully cultivated on the coasts of Spain for the purpose of this manufacture. The following table shows the composition of various kinds of ash, as given by GIRARDIN, RICHARDSON, and others:—

Constituents.	Alicante.	Cherbourg.	Cherbourg.	Unknown.	Unknown.	Spain.	Villeite.	Granville.

Kelp, which was formally prepared on a considerable scale on the coasts of Ireland and the Western coasts and islands of Scotland, is greatly inferior in value to *barilla*. This is the residue of the combustion of sea-weeds and various species of *fuci*, and similar plants. Its composition is very variable, not only as regards the proportion of alkaline carbonate, but of the other constituents; and hence the uncertainty that attended its employment in some of the chemical arts, and particularly in the manufacture of crown glass. Two specimens—the first from Heisker, the second from Rona, both in the Isle of Skye—analysed by URE, gave the following results:—

Soluble	{ Sulphate of soda,	8·0	19·0
	{ Soda as carbonate and sulphide, ..	8·5	5·5
	{ Chlorides of potassium and sodium, ..	36·5	37·5

The native sodas obtained in France are distinguished under various terms, according to the district where extracted. The most valuable is that known as *salicor* or *Narbonne soda*, which is the residue of the combustion of the *Salicornia annua*. It contains from fourteen to fifteen per cent. of the alkaline carbonate. Another kind, also valuable, is *blanquette* or *aiguemorte soda*, extracted

from plants growing on the coasts, among which the most important are the *Salicornia europæa*, the *Salsola tragus*, the *Atriplex portulacoides*, the *Salsola kali*, and the *Statice limonium*. The first-named of these yields the most soda, and all contain abundance of common salt. The amount of carbonate of soda in *blanquette* varies from three to eight per cent. *Varec* or *Normandy soda*, like *kelp*, is the ash of plants belonging to the species *fuci*. This is the least valuable of the French native sodas, but it contains much sulphates of soda and potassa, chlorides of sodium and potassium, and a little iodide of sodium. It is principally extracted for the sake of its potassa salts, and is used in the manufacture of glass and saltpetre. It is also valuable as a source of iodine. The commercial demands for soda are now supplied almost exclusively by an artificial method of production. *Barilla* and *kelp* are used to a small extent in the soap manufacture, as a substitute for chloride of sodium, and in Scotland sea-weeds are still consumed as a source of potassa and of iodine. For the extraction of these the lie obtained from the ash is evaporated, when the potassa and soda salts separate one after the other, and the mother-liquor, distilled with sulphuric acid and peroxide of manganese, yields the iodine.

Generally, the ash of sea-plants, compared with that of those growing on the shore, is not rich in carbonate of soda, but contains much potassa. This fact is not, however, without exceptions, for in the various species of *fuci* soda largely predominates, and the fucoidal

plants are, doubtless, also the principal sources of iodine in those ashes.

Artificial Soda.—Soda Ash.—White Ash.—The production of artificial soda is now one of the most important branches of manufacturing chemistry, although the art was, little more than half a century ago, almost entirely unknown. It may indeed be averred, without fear of contradiction, that since the first application of chemical science to manufacturing operations, few discoveries have been made having such an important bearing, whether considered in relation to social life, to commerce, or to the progress and successful prosecution of the useful arts, as that of the production of carbonate of soda from common salt. It would, indeed, be difficult to exaggerate the immense importance of this manufacture; and probably no more striking proof of this can be given than the enormously increased consumption of this salt since its production at a moderate cost was effected.

The manufacture of soap and of glass; the fictile arts, as well as those of bleaching and dyeing; the production of paper; many metallurgical operations, *et cetera*—are dependent for their successful prosecution upon a supply of carbonate of soda, and the various other substances obtained as by-products in the manufacture; and to meet the consumption of this article, the transformation of chloride of sodium or common salt into carbonate of soda is almost entirely depended upon.

Historical Notice.—It has been already observed that the introduction of artificial soda dates only from a very recent period. It has also been previously mentioned that of all the varieties of native soda, that known as *barilla* is by far the most valuable, containing twenty-five to thirty per cent. of the carbonate. The plant yielding this ash grows most luxuriantly on the coasts of Spain, and was formerly cultivated on a most extensive scale for the purposes of this manufacture; and the ash was produced so abundantly as to supply, not only the native demand, but also that of other countries where either the plants yielding soda were scarce, or if a large quantity of ash was obtained, the amount of soda contained in it was comparatively small.

While it thus happened that other nations were almost entirely dependent upon Spain for a supply of soda, Great Britain produced large quantities of native soda under the form of *kelp*, the manufacture of which was carried on at a very early period on the North and West coasts of Ireland, and later on the Western shores and islands of Scotland. This branch of trade was especially brisk at the commencement of the present century when, to meet the exigencies of the war, high duties were imposed upon the Spanish *barilla*. The annual rental of the kelp shores of the island of North Uist alone amounted at this time to seven thousand pounds; and at one period the entire quantity of *kelp* produced in Scotland, and its adjacent islands, was estimated at more than twenty-five thousand tons annually. Still, the quantity of native soda thus obtained was not sufficient to supply the demands of commerce; and even in 1834, some years after the introduction of artificial soda, *barilla* was imported to the amount of upwards of twelve thousand tons. But more especially was France dependent upon Spain for supplies of

native soda; and when at the time of the French revolution of 1789, during the cessation of the commercial intercourse between France and Spain, the importation of *barilla* was suspended, the National Convention, incited by the proposition of a manufacturer of the name of CARNY, made, in a special proclamation, an appeal to the chemists of France to devise a process by which common salt might be rendered available as a source of soda, and to lay before them whatever plans they knew or could devise for the preparation of soda.

Not only was the importation of *barilla* discontinued, but the supply of potassa was also greatly diminished at this period. All the potassa that could be obtained in France was immediately applied to the production of saltpetre to be consumed in the fabrication of gunpowder; and those branches of trade requiring for their prosecution large supplies of alkali—either potassa or soda—were almost completely at a stand still. But necessity is ever the mother of invention; and the republic mastered the difficulty by an unprecedented development of internal power. To the appeal of the Convention due response was made, and numerous plans were proposed; but of all the processes communicated to the committee intrusted with the examination and execution of the various proposals, the only one deemed likely to be advantageous was that of LEBLANC, and the justness of this decision has been ratified by fifty years' experience; no essential improvement having since been made in the process. The first establishment for prosecuting the manufacture on a large scale, was erected in 1804 at Saint Denis by LEBLANC, and was carried out by him and his partners, DIZÈ and SHÉE. The great French chemist, after having spent all his means in perfecting his plan, was neglected by the government of his own country, and though handsomely rewarded by the British government, at last died in an hospital. In Greece and at Rome statues have since been erected to his memory.

The valuable properties possessed by carbonate of soda were too well known, even at an early date, in England, to allow experimenters to remain idle. In a patent granted to Dr. BRIAN HIGGINS as early as 1781, the Editor finds that he started with common salt, which he decomposed into sulphate of soda and hydrochloric acid by oil of vitriol, in the manner described under SULPHATE OF SODA. The dry sulphate or salt cake obtained was put into a reverberatory furnace, with one-eighth of its weight of coal, and heated till the ingredients were melted, and the sulphate reduced to the state of sulphide. At this stage twice its weight of lead was introduced, and when the metal was melted, the whole was stirred with an iron rod until the sulphur united with the lead, and the fused caustic soda floated in a distinct layer over the surface of the sulphide of lead. The furnace was then tapped to allow the alkali to flow out.

The great expense attending this plan, arising from the high price of lead, *et cetera*, rendered it valueless as a commercial process; but in the same patent HIGGINS states that *iron introduced into the furnace, or other metallic oxides, may be used equally well*. Here, therefore, is clearly developed the principle of LEBLANC'S

process, who merely replaced the *oxide of iron by oxide of calcium* or lime. HIGGINS, therefore, may be considered the *inventor* of the process.

LEBLANC's process, is substantially that practised in Great Britain at the present day. Its introduction into this country was, however, effectually prevented until a considerable period after it began to be adopted in France, by the enormously high duty imposed upon salt, amounting, from the year 1805 until about 1822,

drawings. Fig. 516 is a longitudinal section; Figs. 517, 517½ a plan; and Fig. 518 an end elevation. The furnace is similar in construction to a common reverberatory; but its floor, or *bed*, is divided into two parts, A and B—Fig. 516—B being raised half a brick above A. The former, or that farthest from the fire, is termed the *preparatory* bed, and upon this the materials are first placed and heated to low redness, so as to avoid cooling the furnace; the mass is often indeed in a state of partial fusion before its removal to the other hotter portion of the furnace bed, A. The latter is called the *fluxing* bed, and here the material is speedily brought to a liquid condition; the floor of A is lined internally with the most refractory fire-bricks that can be procured; it is not necessary to be so particular in respect to the floor of B. The arched roof is likewise built with fire-brick; E is the fire space, G the ash pit, and F the flue leading to the chimney.

Fig. 516.

to fifteen shillings per bushel, or about thirty times the cost of the salt. Shortly after the repeal of this impost, the manufacture was commenced on a considerable scale in England by Mr. JAMES MUSPRATT of Liverpool—*vide* SOAP, page 872. Until the year 1830, the soda produced, which was almost wholly consumed in the soap manufacture, was disposed of in the crude condition, under the form of *black ash*. After that period the carbonate of soda was extracted from the black ash produced by lixiviation, and sold, as at present, as a white or soda ash. For about six years after the commencement of the manufacture, the trade remained almost entirely in the hands of the Editor's father. In the year 1836 an important improvement was effected in the carrying out of the process, by the introduction, by Mr. GOSSAGE, of an apparatus for condensing the gaseous hydrochloric acid eliminated during the conversion of the common salt into sulphate of soda.

Many other improvements have been subsequently made, tending to render the process more complete and economical. These will be described in detail in the following pages. The first important operation in the manufacture—the conversion of chloride of sodium into sulphate of soda—has already been fully discussed. The next operation in the process is the production of *black ash*.

Black Ash.—Ball Soda.—The materials used in the production of this ash are perfectly dry sulphate of soda, charcoal, or small coal—slack—and carbonate of lime, either in the form of common limestone or as chalk. These substances require to be brought into a state of fusion together, and this operation is the most important part of the whole soda process.

The details of the furnace arrangements at present in use for this operation are shown by the annexed

When economy of space is a matter of much moment, the opening to the fire space is on one side of the furnace, and the bars reach across; but when it can be allowed, it is preferred to have two sets of fire bars, as shown in Figs. 517, 517½, and 518, and to fire the furnace at the end.

There are two openings into the furnace, C and D,

Fig. 517.

Fig. 517½.

furnished with doors partially supported with weights passing over pulleys.

The walls of the furnace at c and d are bevilled off on the inside, so as to render the furthest parts of the furnace readily accessible by means of the iron rakes and utensils used in working it.

Immediately in front of the openings, c and d, is

Fig. 518.

suspended from the top of the furnace a stout iron rod, with a depression in the centre, so that the heavy rakes used may be supported upon it as a fulcrum.

The furnace walls are strengthened by iron plates, and firmly bound together by iron rods, as seen in the plan and end elevation.

The furnace having been heated to a suitable temperature, a charge, usually consisting of three hundredweights of sulphate of soda, three to three and a quarter hundredweights of crushed limestone or chalk, and two hundredweights of small coal, called *slack*, roughly mixed together, is then thrown on to the upper bed, A, and spread over it, so as to be evenly exposed to the flame of the furnace. A most important consideration is to have the ingredients of the mixture in proper proportions; although in compounding it, manufacturers may advantageously vary the amount of the ingredients, according to the purposes to which the black ash is to be applied. For instance, it is in some cases desired that the black ash produced should yield a considerable proportion of caustic soda, whereas in others, especially when the object of the manufacture is the production of soda crystals, the presence of caustic soda in large quantity is the occasion of great inconvenience.

It is a most difficult task to lay down precise rules for the guidance of the practical man in such cases, owing to the great difference in the materials used by different manufacturers. If the carbonate of lime employed be very fine, the proportions directed to be employed by *LEBLANC* yield a good black ash. These are a thousand parts each of dry sulphate of soda and chalk, and five hundred and fifty of charcoal.

Wood charcoal can rarely be obtained cheaply enough to be used for this purpose, and small coal, such as leaves but little ash, is substituted for it, in which case the quantity used should then be two-thirds of the weight of the salt cake, or even more.

If all the materials taken were perfectly pure the proportions required would be—of sulphate of soda forty-one parts, of carbonate of lime forty-four, and of charcoal fifteen. This accords with the explanation of the process of decomposition given by *DUMAS*; but his theory, as will be shown presently, has been more than once called in question. The proportions of salt cake and limestone or chalk employed, are properly one

hundred parts of the former to one hundred and five, or one hundred and ten, or even one hundred and twenty of the latter; while, as to the proportion of coal, probably not two manufacturers in this country use the same. *URE* recommends ten parts of salt cake, from eleven to twelve parts of chalk or limestone, and five parts of coal; and in a large manufactory near Liverpool, the proportions taken are, thirteen parts of salt cake, nine and a half parts of coal, and fourteen parts of limestone. Some chemists recommend that the materials should all be reduced to coarse powder, and afterwards most intimately mixed by sifting together. This is an unnecessary expense and waste, as the decomposition proceeds quite as successfully when the materials are simply broken into small fragments and mixed in that state.

The operation of fluxing is carried on in the following manner:—The furnace having been properly heated, the charge, differing in quantity according to the dimensions of the furnace, is thrown in upon the preparatory bed, spread evenly over its surface, and when it has become hot, transferred to the fluxing bed by means of an iron spatula or *slice*, shaped somewhat like an oar. The door of the fluxing bed is then closed, so that the heat may exert its full power, and a second charge is immediately placed upon the preparatory bed.

In a short time the charge upon the fluxing bed begins to soften at the surface and form into clots; it should then be turned completely over by the slice, and a fresh surface exposed, until the whole mass appears to have the consistence of dough. Jets of inflamed sulphide of hydrogen and carbonic oxide gases now issue from the various parts of the mass, and the whole should be continually worked about with the slice and an iron rake, so as to equalize the mass, and continually expose fresh surfaces to the action of the fire. When the jets of flame begin to disappear the mass is raked out into iron barrows, each capable of holding a single charge, in which it is allowed to solidify, and in this state it is termed a *ball*. In a furnace of the dimensions above given, the weight of each charge would be about seven hundredweight. Nine of these, the weight of which after decomposition will be about five hundredweight, may be introduced and withdrawn in eight hours, or twenty-seven in twenty-four hours. This is, indeed, the quantity usually worked in that period, but a still greater number of balls may be produced in the same time. The Editor has known nine charges to be introduced and completely decomposed in five and a half hours, and it is important to notice that the black ash so produced yielded its soluble portion with far greater ease than a ball that has remained in the furnace some minutes longer. It is, indeed, important that black ash should be withdrawn from the furnace the moment decomposition is completed, for in this case the mass, after solidification, remains so porous that the soluble portion may be extracted with colder water, and in a shorter period of time, than when closer and heavier black ash is produced. This is one of the characteristics of good black ash; another is that it should contain *no* sulphate of soda, and more especially should it be free from sulphide of sodium. It should be of a blackish-grey color;

when treated with water the filtrate should be colorless, or with the slightest green tinge; and should yield about twenty-four per cent. of available alkali.

A patent was obtained in 1853 by ELLIOT and RUSSELL for an improved furnace, to be used in place of the usual black-ash furnace. This improvement consists in the substitution of a revolving cylinder of iron, lined with fire-bricks, for the chambers of the ordinary furnace, and with the later modifications by Messrs. STEVENSON and WILLIAMSON, of the Jarrow Chemical Works, South Shields, Newcastle-on-Tyne. Its advantages appear to be of sufficient importance to induce its general adoption by soda manufacturers.

In the annexed drawing—Fig. 519—A is the cylinder made of malleable-iron plates, lined with fire-bricks, some

portions of the lining being made to project in the form of shelves beyond the inner periphery of the brick cylinder, the shelves being intended to assist in mixing the charge. The malleable-iron cylinder is formed in two cast-iron rings, B B, which rest and run upon strong iron rollers, C C, supported in proper bearings. The cylinder is made to revolve slowly by means of a pair of pulleys and a train of wheels, as shown in the figure. The internal dimensions of the cylinder are—length thirteen feet, and diameter seven feet; D is the coal-burning furnace, from which flame escapes through a lateral orifice, corresponding with openings, E F, in the ends of the cylinder; and the flame, having traversed the chamber of the furnace, passes over the contents of a boiling-down pan, G, to the chimney.

Fig. 519.

When it is desired to charge the cylinder, the aperture, H, is raised to the position shown in the figure corresponding with a hopper containing the charge, and the charge is at once introduced. When the working of the charge is finished, the aperture, H, being unstopped, and the position of the cylinder reversed, it is run into a number of iron waggons, linked together, and brought consecutively under the aperture. With a cylinder of the above-stated dimensions the proper charge contains twenty-four hundredweights of sulphate of soda, with the usual proportions of chalk and small coal.

According to the invention of STEVENSON and WILLIAMSON, as described in their specification, the chalk is first introduced into the cylinder with a portion of the coal, and heat is applied from the coal furnace. During this period, which continues about an hour and a half, it is only needful to cause the cylinder to revolve about once in five minutes, and the same rate of speed is sufficient until the decomposition of the charge approaches completion, when it is found necessary to increase the number of revolutions to the rate of one in two minutes. The effect of the previous heating of the chalk and coal is to convert the greater part of the chalk into caustic lime. When this is effected, the charge of sulphate of soda with the remaining portion of small coal is added; and the rotating motion, together with the application of heat, being continued during a further period of about an hour, the decomposition is completed, and the charge

is ready for withdrawal. In this manner the furnace works off a charge every three hours, or decomposes nearly ten tons of sulphate of soda per diem, which is almost equal to the work of three ordinary black-ash furnaces.

The patentees state the advantages resulting from their improved furnace and mode of working to be—

1. The continual motion of the furnace causes its contents to become heated with perfect uniformity, so that no part of the charge ever attains an excessive temperature, and thus the loss of soda from volatilization is much diminished.

2. The mixing of the materials for the charge is effected without requiring the furnace to be opened for the introduction of implements, consequently without a current of air being drawn through the furnace during such mixing, thus providing for the atmosphere in the furnace being constantly devoid of free oxygen.

3. From the much larger quantity of work effected by the patent furnace at one time, a smaller number of skilled workmen is sufficient, and the risk of bad work is diminished, and a more complete decomposition of the sulphate of soda is insured by the more perfect mixing.

4. The waste of soda by absorption into the beds of the ordinary furnaces is avoided, and no tools being used in the process of mixing, the surface of the brick lining is less subject to injury from working than the bottoms of reverberatory furnaces.

Theory of the Decomposition.—The conversion of

the sulphate into carbonate of soda by the above-described method of **LEBLANC** is a very complicated process of decomposition. Some French chemists, however, amongst whom **DUMAS** may be mentioned as the foremost, take a very simple view of the case. They suppose that when sulphate of soda, carbonate of lime, and charcoal are fused together in the proportions given above, in the first place the sulphate of soda and carbonate of lime react upon each other, producing carbonate of soda and sulphate of lime thus:—

The sulphate of lime, in contact with incandescent charcoal, yields its oxygen to the latter element, and carbonic oxide, or a mixture of this and carbonic acid is evolved, leaving protosulphide of calcium in admixture with the carbonate of soda previously produced.

If carbon is present in greater proportion, it is taken up by the carbonic acid gas, which thereby passes into the state of carbonic oxide—

Supposing this to be a true statement of the transformations, the subsequent decomposition—namely, the reaction of carbonate of lime upon bisulphide of sodium—must also be far more complicated than is usually supposed. It is exceedingly difficult to arrive at any positive conclusion from the views of different chemists upon this subject. It is certain, however, that the calcination of sulphate of soda with both coal and carbonate of lime at the same time, is by no means essential to the process; if desirable, the sulphate might first be treated with coal alone, and the resulting sulphide or mixture of sulphide and carbonate be afterwards calcined with carbonate of lime.

Composition of Black Ash.—Probably in no other department of chemistry does a greater difference of opinion exist among theorists, than as to the true composition of black ash. The principal, but by no means the sole discrepancy in their statements, is found in their different views of the composition of the insoluble lime salt. When a mixture of sulphide of calcium and carbonate of soda in *equivalent proportions* is treated with water, insoluble carbonate of lime is formed, and sulphide of sodium is obtained in solution. But if to the mixture of carbonate of soda and sulphide of calcium a portion of lime be added, and the compound be then affused with water, the soda salt, partially

Other chemists take a different view of the decomposition. According to **GMELIN**, the sulphate of soda is reduced by the charcoal to the state of sulphide of sodium, with evolution of carbonic oxide gas; and the sulphide of sodium so produced is converted by the carbonate of lime into sulphide of calcium and carbonate of soda; and when three equivalents of carbonate of lime are used to two of sulphate of soda, the result is shown in the annexed equation:—

In the statement of the result of the decomposition, **DUMAS** and **GMELIN** agree precisely; they differ, however, as to the mode by which the result is obtained. **LIEBIG** shows the action of charcoal upon sulphate of soda to be far more complex than as stated by **GMELIN**, and gives the following diagram in elucidation of his views:—

deprived of its carbonic acid, alone dissolves, and the sulphide of calcium remains unaltered.

The question to be solved, therefore, is—in what manner does the free lime prevent the decomposition that would otherwise ensue? Many chemists explain the difficulty, by supposing that the lime— Ca O —enters into combination with the sulphide of calcium. In the first place, however, it must be borne in mind that this supposed compound has never yet been isolated, so that its precise composition cannot, therefore, be ascertained.

DUMAS, and some others assume it to be a combination of two equivalents of sulphide of calcium with one equivalent of lime— $2 \text{ Ca S} + \text{Ca O}$. **UNGER**, reviewing **DUMAS**' theory of the process of its formation, considers it much more probable that it is a compound of three equivalents of sulphide of calcium with one equivalent of lime— $3 \text{ Ca S} + \text{Ca O}$ —a formula also assigned to it by **PAYEN**, and adopted by many others. **ROSÉ** regards it as composed of one equivalent of sulphide of calcium, with one of hydrate of lime— $\text{Ca S} + \text{Ca O, HO}$.

The conclusion that combination of sulphide of calcium with lime does ensue, appears to have been arrived at, not from an analysis of the pure compound, for, as mentioned above, it has never yet been obtained, but simply because, in the presence of free lime, the sulphide of calcium *does not dissolve* when treated with water. This is indeed the only argument stated by **DUMAS** to account for the existence of his $2 \text{ Ca S} + \text{Ca O}$; and certainly the fact that an additional proportion of lime in the preparation of black ash does render the sulphide of calcium more insoluble, seems a power-

ful argument for the existence of this or a similar compound. UNGER, however, reasoning analogically, argues that because ROSÉ obtained a salt having the formula $3 \text{ Ba S}, \text{ Ba O}, 28 \text{ HO}$, the compound— $3 \text{ Ca S}, \text{ Ca O}$ —though free from water, might also be supposed to exist. This, although affording a strong presumption, cannot be accepted as a conclusive proof; and still the question remains—If sulphide of calcium is more soluble in the presence of free lime than in the pure state, why is this the case? In an investigation into the composition of black ash performed a few months ago by Mr. J. W. KYNASTON in the Editor's laboratory, it was found that when the ash was treated with water, and allowed to remain for some time undisturbed, the lime previously existing in the ash in the free state, by acting upon the solution of carbonate of soda, eliminated caustic soda, *itself becoming wholly converted into carbonate*. This, if not conclusive proof of the non-existence of the hitherto assumed compounds of sulphide of calcium and lime, at least shows that the stability of the sulphide of calcium of black ash, when treated with water, is not to be ascribed to the production of any such compound. In this view Mr. KYNASTON is supported by the observations of GOSSAGE, than whom probably no one ever performed so numerous a series of experiments upon black ash, and more especially upon its insoluble portion. Mr. GOSSAGE states that he has long held this view, and, indeed, founded upon it a process for the recovery of the sulphur from the insoluble portion of the ash, to which further reference will shortly be made. Mr. KYNASTON suggests that, instead of the combination of sulphide of calcium with lime, a compound may exist of sulphide of calcium with carbonate of lime, and having the formula $2 \text{ Ca S}, \text{ Ca O}, \text{ C O}_2$. Were further evidence required, an additional proof that the whole, or at least the greater part, of the free lime of black ash is converted into carbonate, when the ash is treated with water, is the fact of the existence of so large a proportion of caustic soda in black-ash liquor, and the presence of which cannot be satisfactorily explained in any other way. Some chemists—indeed by far the greater number who have written upon the subject—do give hydrate of soda as a constituent of black ash. It will not, however, be difficult to show the fallacy of this. KNAPP accounts for the proportion of caustic acid, by supposing a portion of the carbonate of lime to be burnt and converted into the caustic state, before the decomposition of the soda salt is effected; the caustic lime, then acting upon the sulphide of sodium, produces sulphide of calcium and caustic soda:—

One may be permitted to doubt whether this reaction would take place under the circumstances. Carbonate of soda, treated in solution with caustic lime, gives rise to the formation of caustic soda and the insoluble carbonate of lime. But if caustic soda and carbonate of lime be fused together, carbonate of soda and caustic lime are produced. So if a mixture of caustic soda and sulphide of calcium be fused together, sulphide of

sodium and caustic lime are formed, $\text{Na O}, \text{ Ca S}, = \text{Na S}, \text{ Ca O}$; but if the resulting mass be treated with water, caustic soda and sulphide of calcium are reproduced. It cannot be reasonably supposed, that when in the case of the pure salts the above-mentioned reaction is well known to take place, in the production of black ash, exactly the reverse action should ensue with the same salts and by a similar mode of treatment. Yet it is well known that in the preparation of black ash, caustic lime may be, and in the early days of the manufacture in this country was, used instead of carbonate of lime. But in such a case a predisposing cause, if the term may be allowed, determines the reaction. When zinc and water are placed in contact, the water is not decomposed; but if an acid be added, decomposition of the water rapidly takes place. So when sulphate of sodium and lime are fused together no change occurs; but when charcoal is also present, and hot air is blown upon the mass as in the reverberatory black-ash furnace, decomposition immediately follows.

Carbonic acid is here the *predisposing cause*, just as sulphuric acid is in the case of zinc and water. The success of this soda process is, indeed, in no small degree owing to the remarkable affinity of soda in the fused state for carbonic acid; and this is so great, that even supposing caustic soda to exist in the black ash at any time during its preparation, it could not remain more than a few moments uncombined in the atmosphere so highly charged with that acid. It is further to be noticed that all those analysts who state hydrate of soda to be a constituent of black ash, also include *carbonate of lime* amongst the ingredients. But what an inconsistency to suppose that hydrate of soda and carbonate of lime can exist, after fusion together for such a length of time as in the preparation of black ash, when the two salts so readily decompose at a much lower temperature than that to which the mass is subjected. Still another argument against the existence of caustic soda in black ash presents itself, if the theory of DUMAS and others of the French school be accepted as the true one. These explain the reaction, by supposing that the sulphate of soda and carbonate of lime first decompose the bases, exchanging acids, and that the sulphate of lime so formed is afterwards reduced to sulphide of calcium by the charcoal. In this case *no caustic soda can have been formed*; and as carbonic acid once combined with soda cannot be again removed by simple heating, of course no caustic soda can be produced. In conclusion, the Editor must again assert, that as yet no sufficiently satisfactory proof has been put forward to show *hydrate of soda to be a constituent of black ash*; while, on the other hand, its existence in the black-ash liquors is quite consistent with the views expressed above. But if this be admitted, the theory that the sulphide of calcium owes its insolubility and permanence to its having entered into combination with free lime, is of course disproved. The fact does not indeed require such a far-fetched explanation. Protosulphide of calcium is itself *very insoluble*, bisulphide of calcium is *readily soluble*, and all that it appears necessary to guard against is the formation of bisulphide of cal-

cium, or rather perhaps of bihydrosulphate of lime, which is so liable to be produced.

Whether a sulphite and hyposulphite actually exist in black ash, is a question that hardly admits of proof. They are included in the analyses of several investigators, and the researches of Mr. KYNASTON certainly lead to the same conclusion. Still the probability of the formation of these, subsequent to the removal of the black ash from the furnace, is so obvious, that until the point has been conclusively determined, it is better not to express any positive opinion. Black-ash liquors certainly contain both salts. Sulphate of soda and ferrocyanide of sodium are frequently constituents of black ash, but these are not always present. The Editor has had numerous samples examined which were free from even a trace of either one or the other. The subjoined analyses of this highly complex mixture are by UNGER and RICHARDSON. Both, it will be seen, assume the existence of a compound of sulphide of calcium and lime, and also of caustic soda.

Annexed is another analysis of black ash, just made by Mr. MARTIN MURPHY, the Editor's talented assistant, and whose aid in scientific and literary matters for twelve years he has found of the utmost service :—

Soda,	25.388
Lime, chiefly existing as sulphide,	35.484
Carbonic acid,	17.599
Sulphur,	14.747
Sulphuric acid,	0.421
Iron,	3.020
Alumina,	1.165
Silicic acid,	0.945
Chlorine,	0.794
Charcoal,	5.724
Ultramarine and sand,	1.659

The preceding numbers correspond with the following order of combination :—

Carbonate of soda,	41.489
Sulphate of soda,	0.748
Chloride of sodium,	1.308
Aluminate of soda,	0.392
Silicate of soda,	1.162
Sulphide of calcium,	33.193
Caustic lime,	9.320
Carbonate of lime,	0.857
Sesquioxide of iron,	3.020
Alumina,	1.020
Charcoal,	4.724
Sand, et cetera,	2.259

100.000

The characteristics of good black ash are as follows :—It should be of a blackish-grey color, and with open pores, similar to pumice-stone, so that a liquid may easily penetrate its substance. It should contain from twenty to twenty-four per cent. of available soda, and should be free, or contain only a slight trace of sulphate of soda. When the solution obtained by lixiviating a portion is acidified, merely a faint smell of sulphide of hydrogen should be perceptible.

Lixiviation of the Black Ash.—This is the next operation in the process of manufacture, and is the first step towards the preparation of pure soda from black ash. Its object is the separation of the soluble constituents from the calcareous and other insoluble matters present. To effect this the balls of crude soda, a day or two after preparation, are broken to fragments and thrown into iron vats. By some it is recommended, first, to crush or grind the ash under upright millstones, and afterwards to sift it, or else to crumble it by exposure to hot vapor. With this view, the ash is sprinkled with water in a tolerably hot furnace, where, in the atmosphere of vapor, it soon swells up and falls to pieces. If the ash has been properly prepared this proceeding is quite unnecessary, and indeed objectionable on other grounds than the expense and labor required. With ash that has been allowed to remain too long in the furnace it may, however, be necessary to heat it in such a manner, otherwise the extraction of the soluble ingredient occupies too long a period of time; and it must be borne in mind that the longer the liquor is allowed to remain in contact with the insoluble portion of the ash, or the *soda water*, the greater the amount of sulphide of sodium in the solution, and this must be subsequently got rid of, or the ash will be unfit for use.

The vats used in the process of lixiviation are of iron, and of considerable size, and are so arranged as to allow the separation of the soluble constituents of the ash with the smallest possible proportion of water.

But although, as KNAPP observes, it is desirable, on the one hand, to use as little water as possible, yet it is equally necessary on the other hand to dissolve out every particle of alkali from the residue. In this, as in all other similar cases, both objects have been obtained by one and the same ingenious method.

The difficulty is obvious; if too little water be used in the first instance, a portion will remain undissolved. In the contrary case all the alkali will be dissolved, but, as at first, the whole solution cannot be drawn off; for a considerable quantity is kept back by the spongy

residue. It is, therefore, impossible in any case to obtain the whole quantity of soluble matter with one portion of water; a second, third, and fourth portion will be required, each of which will contain a less quantity in solution, so that, altogether, there will be a vast excess of liquid. The contrivance by which this difficulty is overcome, depends upon an uninterrupted continuance of the process, and consists in using the same water which was employed for the first infusion, with fresh portions of crude ash, until the solution has acquired the proper strength for boiling.

Just in the same manner every second or subsequent infusion can be increased in strength, so that none but sufficiently concentrated lie is supplied to the evaporating pan. Suppose that a certain quantity of water has taken up eight per cent. from the first portion of the soda, it will take up as much more from the second, and leave it containing sixteen per cent.; from the third portion it will be drawn off with twenty-four per cent., and so on.

The lixiviation was formerly effected in vats so placed at different elevations, that weak liquors resulting from partly lixiviated ash flowed upon ash contained in a fresh set vat; but in using such apparatus, the manufacturer had to remove the partially lixiviated ash into higher vats, and yet the strongest liquors obtained rarely exceeded a specific gravity of 1150°, and consequently a very large quantity of water had to be evaporated to obtain dry salt. A very ingenious and scientific apparatus was invented and applied successfully by the celebrated French chemist, CLEMENT DESORMES. This apparatus provided for obtaining solutions of much higher gravity, but necessitated the employment of much manual labor, and also occupied a large space. The lixiviating apparatus which is now universally adopted by the manufacturers of soda in this country, the Editor knows to be a foreign invention, which was introduced

by Mr. C. T. DUNLOP into the St. Rollox Chemical Works, Glasgow, about the year 1843. This apparatus from its extreme simplicity, correct scientific principles, and the perfect manner in which the lixiviation is effected by its use, appears to fulfil all the conditions which can be desired in this process.

The apparatus is represented in Fig. 520, and may be described as consisting of a rectangular vessel about twenty-four feet long by twelve feet wide, and five deep, having three partitions, H H, dividing it into four vats, A, B, C, D, of twelve feet by six feet. Perforated false bottoms, E E, are supported about three inches above the bottom of the vats, on which the black ash is thrown in lumps. Each vat is furnished with a vertical pipe, F, five feet long, the lower end of which is open, and communicates with the space below the false bottom. About one foot six inches from the upper end of this pipe a short branch is provided, and this branch is bolted to the side plate of the vat; an opening being made in the side plate, to correspond with that in the branch. By these means a communication is effected between the lower part of one vat, and the upper portion of another. The upper part of the pipe, F, is enlarged; and at the lower part of this portion, a conical seating is provided, which admits of the passage being closed by a plug, or of a short pump being applied to withdraw the fluid contents of the vat.

When in regular use, the four vats will contain black ash at various stages of lixiviation, diffused in their corresponding liquors—one being filled with fresh balls; and another, furthest distant from it in the series, containing residuum all but deprived of its soluble matter. A supply of warm water is run upon the first and nearly spent vat; and this, after permeating through the residuum and becoming impregnated with alkali, rises through the pipe F, and flows into the upper part of the second vat, through the contents of

Fig. 520.

which it passes, taking up more alkali, and rising again by a similar pipe, gains access to the third vat, and so on into the fourth vat, in which the liquor becomes fully saturated by its contact with the fresh balls. The flow of liquor from the last vat may be intermittent, but it is preferable that it should be continuous; the supply of warm water to the first vat being also continuous, and this vat kept constantly filled. When it is found that the liquor proceeding from the first vat contains scarcely any alkali, this vat is shut off from the series; and the remaining liquor being pumped out, the residuum is removed, and the vat filled with fresh balls. This vat now becomes the fourth of the series, and receives liquor from that which was previ-

ously the fourth, by means of a pipe leading externally from the lower part of the latter to its upper part. When the vats are arranged in a square of four as shown in Fig. 521, in place of four longitudinally, this external pipe is not needed. In this manner each of the vats becomes consecutively the one to be discharged, and to be refilled with fresh balls.

In large establishments, a series of sixteen or more vats in a double row are employed, and these may be constructed by fixing longitudinal and transverse partitions in one large vessel.

By the provisions of this highly scientific apparatus, it becomes no longer needful to remove the black ash during the process of lixiviation; which removal was

previously attended with much labor, injurious exposure to the oxidising influence of the air, and great diminution of the permeability of the mass. The residuum in the above admirable arrangement, is constantly

Fig. 521.

supported by the fluid in which it is immersed, and thus kept in a condition highly favorable to its permeability; and the solvent is caused to percolate through the contents of the whole series without the cost of pumping. Practically, the advantages have been found to comprise a much more perfect abstraction of the soluble parts of black ash, and the obtaining of solutions requiring less than half the evaporation formerly necessary; indeed, so perfect is the process of lixiviation, that scarce one-tenth per cent. of soda is left in the residue.

In some alkali works, to assist the solvent power of the water employed in the lixiviation of black ash, it is usual to heat it to about 90° to 100° . This end may be conveniently attained by passing the water through a coil of pipes contained in a steam boiler. The practice of heating the water, though it undoubtedly aids the process of lixiviation, is nevertheless very objectionable, principally because sulphide of calcium is dissolved and decomposed by hot water, giving rise to the formation of sulphide of sodium, and the hotter the water the greater will this proportion of sulphide be, or rather of the double sulphide of sodium and iron contained in the vat liquor.

The temperature of the water, it must also be observed, always rises considerably— 20° to 30° or more—on coming in contact with the fresh black ash in the fresh vat, owing to the powerful affinity of caustic lime for that liquid to produce hydrate of lime. In summer the liquor frequently becomes so hot as to render necessary its withdrawal considerably below the point of saturation, otherwise the ash obtained on evaporation would be so strongly impregnated with sulphide, that it would be quite inapplicable to many purposes.

If the temperature of the liquor should not rise higher than from 110° to 120° , it may remain in contact with the ash until of specific gravity $1.225 = 45^{\circ}$ Twaddell; in the contrary case it should be withdrawn

at a density of $1.200 = 40^{\circ}$ Twaddell, or even still lower. Water is allowed to run into the weak vat until the density of the liquor passing through is reduced to 1.10 to $1.15 = 2^{\circ}$ to 3° Twaddell, and the insoluble matters remaining should, after being dried, contain not more than 0.2 or 0.3 of available soda. This last portion, if extracted, would contain so large a proportion of sulphate and other salts of lime, that on coming into contact with the ash in the next vat, it would decompose and render valueless more than an equivalent proportion of soda.

The composition of vat refuse—soda waste—according to UNGER's analysis is as follows:—

Carbonate of lime,.....	19.56
Oxysulphide of calcium, $3 \text{ Ca S} + \text{Ca O}$,	32.80
Sulphate of lime,.....	3.69
Hydrosulphite of lime,	4.12
Hydrate of lime,	10.69
Bisulphide of calcium,	4.67
Sulphide of calcium,	3.25
Sulphide of sodium,	1.78
Oxide of iron,	3.70
Silicate of manganese,	6.91
Charcoal,	2.60
Sand,	3.09
Water,	3.45

100.31

The sample of waste examined by UNGER must have been some time exposed to the air. When fresh it contains, according to the Editor's observations, *no bisulphide of calcium*, and but little hydrate of lime either free or in combination. The sulphate of lime also is wholly formed, subsequent to the removal of the soluble constituents of the ash. After being kept for some time only partially dried, a large quantity of sulphite and hyposulphite of lime is also produced, and the mass becomes of a dirty white color, with streaks of a beautiful blue color, running through it. The liquor containing in solution the salts of soda removed from the black ash, as it is withdrawn from the vats, is conducted into a series of settlers or iron vats. In these it is allowed to rest for some hours, to deposit any impurities that may be held in suspension. It is then pumped into a spacious cistern or reservoir, so elevated that, by means of pipes, the liquors may be distributed to the concentrating pans and furnaces.

EVAPORATION OF THE LIE.—The process of concentration is carried on in two different ways. Most commonly the solutions are evaporated and the residue calcined in the same reverberatory furnace, known as the *white-ash furnace*, whose extreme length should be about eighteen feet, and the breadth about nine feet. Its interior is lined with fire bricks, between which and the external masonry is placed a partition of sheet iron. By the application of heat in this manner, the evaporation proceeds rapidly, quietly, and at a very moderate expense of fuel. The waste heat from the black-ash furnaces is frequently applied to the evaporation of vat liquors. In this case, an iron pan termed the *salting pan*, in shape similar to the furnace above described, is placed at the end of the black-ash furnace next to the raised bed. The evaporation proceeds rapidly as with the ordinary white-ash furnace; but the mass of ash is not allowed to become completely dry. As soon as the contents of the pan have attained

the consistence of mortar, they are raked out into a large iron called the *drainer*, furnished with a false perforated bottom, to allow the mother liquor to drain from the crystals. The drained mass is next collected and introduced into a reverberatory furnace, named the *finishing furnace*, in which it is moderately calcined, and at the same time dexterously worked about in all directions so as to bring every part of it in contact with the air, and within the action of the flame. The mother liquor or draining from the *salts*, which contains nearly all the caustic soda and sulphide of sodium and iron, as well as the excess of foreign salts, sulphate of soda and chloride of sodium, *et cetera*, is in some works returned to the salting pans with the next charge of fresh liquor; in others it is evaporated *per se*, and the residue is afterwards heated to redness, mixed with saw-dust or coal-dust in reverberatory furnaces. During the process of calcination the sulphur of the sulphide of sodium escapes in some form of combination, and carbonate of soda is produced; the caustic soda also quickly combines with carbonic acid to produce the same salt, and the sulphate of soda is reduced at the same time to sulphide of sodium, and undergoes a similar change.

In manufactories where caustic soda is produced in a marketable form, it is principally extracted from the mother liquors above-mentioned.

The other method of conducting the evaporation of vat liquors is by means of iron pans, with the fire and heated air applied beneath. These—named *fishing pans*—are of considerable size, and shaped somewhat similar to a boat. They may be heated by a fire used solely for the purpose; in which case to prevent injury to the pan, the arch of the furnace should be continued for some distance beneath, or the pan may be placed at the end of the black-ash furnace farthest from the fire, just as with the salting pan, except that the heated air is made to pass under instead of over the pan. The evaporation is rapidly conducted by this method; and when the lie becomes concentrated to a certain strength, small crystals of monohydrated carbonate of soda— $\text{Na O, CO}_2, \text{HO}$ —constantly fall to the bottom, and as quickly as they fall are raked together to the end of the pan farthest from the source of heat, and then scooped or *fished* out by means of perforated iron shovels. After being allowed some time to drain, the salts so obtained are washed with fresh vat liquor, and then removed a reverberatory furnace, and all worked about until sufficiently dry. The deep-red mother liquor is either applied to the production of caustic soda or evaporated, and the residue heated with sawdust as before directed.

In some alkali works the evaporation of black-ash liquors is conducted in a series of pans, three or four in number, or rather in one pan separated into three or four compartments; in the first, that is, the one at the greatest distance from the source of heat, the solutions are heated to the point of ebullition; in the next, or the two next, the liquors are concentrated until saturated while hot; and in that immediately in contact with the fire, the concentrated liquors are evaporated either to dryness, or until nearly the whole of the carbonate of soda is deposited from solution, and this is afterwards dried in a reverberatory furnace as before.

In the year 1853 an improved mode of concentrating black-ash liquors for the purpose of obtaining salts therefrom suitable for the manufacture of soda ash, was invented by Mr. GOSSAGE, and secured by patent. The following description of the method is in the words of the patentee, and is extracted from the specification:—A long iron pan is provided and heated, either by means of a special fire underneath the same, or by waste heat proceeding from the alkali furnaces. A second long pan is placed contiguous to the first, but to this no heat is to be applied; a channel of communication is provided, and having introduced a suitable quantity of black-ash liquor into both pans, heat is applied to the first pan, so as to produce concentration of the liquor. A continued circulation of the solution through the two pans is effected by pumping or otherwise transferring liquor from the second into the first pan, at the end opposite to that at which the channel of communication exists. By this arrangement the liquors become so concentrated in the first pan as to contain more salts when in a heated state than they can retain in solution at a lower temperature, and therefore as the liquors flowing through the second pan become reduced in temperature, salts are deposited in this pan, and the liquors circulate again through the first pan as required, so as to keep a suitable quantity in the apparatus.

In the process of concentration by the ordinary method in a single pan, the salts, as they are deposited from the solution, collect at the bottom, and form a compact mass of a greater or less thickness, and the heat being continued owing to the bad conducting power of the deposited salts, the part of the pan immediately over the fire, if constant attention is not exerted, frequently becomes heated almost to redness; and if by any means the colder liquid comes in contact with this at so high a temperature, not only is the solution violently thrown from the pan, occasioning considerable loss of liquor, but often the latter becomes cracked, and, of course, is rendered useless until repaired. The advantages of Mr. GOSSAGE's apparatus will therefore be at once apparent, since by his mode of arrangement none, or at least only a small deposition of salts, can take place in the pan to which heat is applied. The patent to which reference has just been made, also includes an improved mode of concentrating black-ash liquors, when it is desired to obtain therefrom in a remarkable state the caustic soda they contain. The apparatus employed consists of an oblong vertical tower, made of iron plates, to the inside of which tower is adapted a number of iron shelves, placed at such an inclination that fluid will flow freely down the same. One of these shelves is attached to one end and to both sides of the tower, leaving a space of about three inches in width between it and the other end. The next shelf is attached a few inches below the first to the opposite end and to the two sides of the tower, leaving the same space between it and the other end. In this manner each alternate shelf is attached to an opposite end of the tower, and the arrangement is such that a supply of fluid introduced on the upper part of the first inclined shelf flows down the same, and is delivered on the upper part of the second shelf, and after flowing over

this reaches a third, and so on consecutively over the whole number of shelves contained in the tower. By these means the fluid employed may be exposed, in thin sheets or films, to the evaporating action of heated air passing through the tower. A supply of heated air is provided by any of the ordinary methods, and the apparatus is connected with the previously mentioned tower, at or near its lower part; and to occasion a large quantity of heated air to pass through, the upper part of the tower is connected with a strong chimney draft. The liquid to be evaporated is introduced into the tower in such a manner that it becomes distributed nearly equally over the uppermost shelf, from which it flows in the same manner over the succeeding shelves, and, exposed to the evaporating action of highly heated air during its course, becomes so heated and concentrated as to contain more salts than it can retain in solution at a lower temperature. A channel of communication from the lower part of the tower is provided, through which the hot concentrated fluid is conveyed to two iron pans; in flowing through these it becomes cooled so as to deposit salts, and the remaining fluid is then elevated by means of a pump from the coolest part of the pans and caused to pass again through the tower.

The inventor prefers to apply this mode of concentration for obtaining soda from vat liquors, to such liquors as have been already deprived of a considerable portion of the carbonate of soda previously contained therein. The circulation of these liquors through the tower is continued until it is found that the whole, or nearly the whole, of the carbonate of soda is removed, when the liquor is separated from the deposited salts, and by further evaporation in an iron pan solid hydrate of soda is obtained. The separated salts, after being washed, are transferred to a reverberatory furnace and completely dried. The product of these operations, whichever of the foregoing be adopted, is the *white ash* or *soda ash* of commerce. When properly prepared it contains fifty-three or fifty-four per cent. of available soda, two or three of which exist in the form of hydrate, and the rest as carbonate of soda. A little sulphide of sodium is also present, and some sulphate of soda, chloride of sodium, and minute quantities of other salts.

A new arrangement or apparatus for effecting the evaporation of black-ash liquors has been invented and successfully applied by Mr. D. GAMBLE, at St. Helens, Lancashire. It has been adopted very generally by the Lancashire manufacturers, particularly by those who are makers of solid caustic soda from black-ash liquors by GOSSAGE'S process. Mr. GAMBLE employs a pan of malleable iron, of the form indicated in Fig. 522, having a length of thirty feet, a width of seven feet, and greatest depth two and a half feet. The pan is placed above, or at the end of a black-ash furnace, and is heated by conducting the waste heat of the furnace by flues under the sides of the pan. The form of these sides is such as to afford facilities for separating the salts from the sides of the pan, when these adhere. During the boiling down, the salts are transferred in ladles into perforated drainers.

Mr. GAMBLE was also the first to use centrifugal machines, or hydro-extractors, for separating mother

liquors from salts obtained from black-ash liquors, and by such an apparatus soda ash of fine quality has been

Fig. 522.

obtained, by the first process, without being redissolved and evaporated.

The analyses of soda ash appended were performed by Mr. KYNASTON in the Editor's laboratory. The ash was obtained by evaporating the liquors at once to dryness, and calcining the residue.

	Centesimally represented.	
Carbonate of soda	67.891	73.626
Hydrate of soda	14.245	13.600
Sulphate of soda	4.579	6.127
Chloride of sodium	6.061	4.431

Insoluble matters	0.217	1.579
Water	5.005	..
Ultramarine	0.140	..
	100.297	100.235
Available soda	50.75	54.00

The soda ash prepared by the processes described is, without further treatment, sufficiently pure for almost all the ordinary manufacturing applications of soda. For some purposes, however, and especially for the fabrication of plate glass, or for the production of the crystallized carbonate of soda—soda crystals—the ash made as above requires to be still further purified; and this is most commonly effected by giving it another calcination in a reverberatory furnace, moderately heated, sometimes by a charcoal fire. Or the salts obtained by evaporation of the vat liquors, either in the reverberatory furnace, or in the *fishing pans*, after being thoroughly drained and washed as completely as possible from adhering impurities, either with fresh liquor or with water, are mixed with saw-dust or coal dust, and calcined in a reverberatory furnace.

This calcination is intended to effect the separation of the sulphur from the small proportion of sulphide of sodium still remaining in the ash, and also the combination of all the particles of caustic soda in the ash, with carbonic acid derived from the burning carbonaceous matters introduced.

The heat applied in the first part of this process should not greatly exceed the melting point of lead.

At that temperature the sulphur goes off freely; but at a dull red heat the sulphur, instead of being volatilized, seems to enter into more permanent combination with the alkali.

The ash requires to be worked about with the oar and rake during the whole course of the operation, which usually takes about three or four hours. After the sulphur is expelled as completely as possible, the fire should be gradually urged until the mass attains a dull red heat, and this is continued until every particle of carbon is removed. The product of this operation is usually of a slightly yellowish or bluish-white tinge, and is excellent material for the manufacture of plate glass. The available soda exists wholly in the state of carbonate, and if any, only the most minute trace of sulphide of sodium. It must not be supposed, however, that this result is arrived at without the most careful manipulation, and constant attention to keep the furnace at the proper temperature required in the several stages of the operation. Ash so prepared should not, on exposure to the air for some time, undergo any alteration in hue, and when dissolved in water should yield a perfectly colorless solution. If it answers to these tests, the plate glass manufacturer may rest assured of its applicability to his purpose.

This ash being wholly in the state of carbonate, the amount of available soda contained in it is not quite so great as in some other varieties.

CRYSTALLIZED CARBONATE OF SODA—*Soda Crystals.*—This salt is prepared by dissolving soda ash, obtained as above, in hot water to the point of saturation, and the solution after reposing for some time is run into shallow pans of cast-iron or of wood, lined with sheet-lead, and allowed to remain at rest until the crystallization is completed. That the operation may be successful in a pecuniary point of view, it is essential that the salt be obtained perfectly colorless by a single crystallization. It is, therefore, necessary to observe particular care in the several operations, and especially in the selection of the ash to be dissolved. Nor is it by any means unimportant that the water used should be as free as possible from carbonate of iron and the salts of the alkaline earths. The ash most suitable is that prepared by the method last described. The alkali contained in it must exist wholly as carbonate. Sulphide of sodium must not be present, even in the smallest proportion; it should be as free as possible from carbonate of lime, and on exposure to the air should not undergo the slightest alteration in color. The solution is effected in different ways by different manufacturers. In the mode now most commonly employed, the lie is heated by means of steam blown into it. The dissolving pan, which is of iron, should be of such a size that sufficient ash may be treated at one operation to yield two, three, or four tons of crystals. Water being run in to about two-thirds full, it is heated to nearly ebullition, and ash is then thrown in, the injection of steam being continued until the solution has a specific gravity of $1.225 = 45^\circ$ Twaddell. It is then siphoned into a capacious iron vessel termed the settler, where it is allowed to remain twelve or fourteen hours to deposit any insoluble matters that may be present. The clarified liquor is

now conducted to a boiler placed over an open fire, where it is heated and kept in a state of ebullition until the density becomes about $1.275 = 55^\circ$ Twaddell. At this point it is again run off to the settlers, a pailful of solution of bleaching powder, or of chalk and water, or a mixture of these, is thrown in to aid the deposition of the impurities, and the whole is allowed to remain until the temperature is reduced to about 92° . At a little lower degree of heat crystals begin to be formed; but before this can take place the liquor is conveyed by means of sluices to the crystallizing pans or *cones*, which are of such a size as to contain sufficient liquor to give from a ton to a ton and a half of the crystallized salt. The annexed engraving shows the manner in which they are arranged in the crystallizing house.

To determine the formation of a larger quantity of very pure crystals, iron rods or bars are laid across the cones, and the crust that forms at the surface of the liquid, adhering to these, is prevented from falling, and will sustain also the mass of crystals that grow immediately beneath it. After nine or ten days—the length of time varying with the season—the crystallization may be considered complete. The mother liquor is then siphoned off, and by evaporation and calcination of the residue, a very white ash is obtained, containing about sixty-five per cent. of carbonate of soda, the other thirty-five being principally sulphate of soda and chloride of sodium. The crystals are allowed to remain a short time in the cones after the removal of the mother liquor, so as to drain and become dry, and are then taken out to be packed.

In some alkali works the soda ash, instead of being treated as above, is dissolved at once by the aid of steam, until the solution has attained a density of $1.275 = 55^\circ$ Twaddell. It is then drawn off to the settlers, a quantity of bleaching powder or chalk added, and when the temperature is near 92° , conveyed to the cones. From some varieties of ash, however, the impurities are not so readily separated, and it is necessary to substitute the process above given. The slimy deposit from the settlers with the adhering liquors, is either returned to the dissolving pan, or when collected in quantity is mixed with fresh water, boiled by means of steam; and the solution, after depositing the gross impurities, is added to the mother liquor from the crystals, and evaporated with it to dryness.

Though the process for the manufacture of soda ash, as detailed above, is very complete, and will probably never be superseded by any other method essentially different, still no one would think of asserting the impossibility of effecting any improvement. Many other modes of manufacture and several improvements of the old methods have been suggested, some of which deserve a brief notice.

A process invented by Mr. GOSSAGE, and for which he obtained a patent bearing date May, 1853, has for its object the purification of the black-ash liquors; firstly, by the oxidation of the sulphide of sodium; and, secondly, the separation of ferrocyanide of sodium from such liquors. During the ordinary process of evaporating black-ash liquors to dryness, and

roasting the product so obtained, the sulphide of iron and the iron of the ferrocyanide of sodium become converted into oxide of iron; and this substance communicates an objectionable color to the soda ash produced, rendering it unfit for certain applications.

The sulphide of iron being held in solution by sulphide of sodium, if the latter salt be converted by oxidation into hyposulphite— NaO , S_2O_2 —sulphite— NaO , SO_2 —or sulphate of soda— NaO , SO_3 —the sulphide of iron set free from combination becomes insoluble, and may be separated from the liquors by subsidence or filtration. In Mr. GOSSAGE'S process, as stated in the specification of his patent, the oxidation of the sulphide of sodium in black-ash liquors is effected by causing them to absorb atmospheric oxygen. To effect this as quickly as possible the liquors are made to pass through a high tower, termed by the inventor an *oxidising tower*, which is filled with small pieces of coke, or other suitable material; and while the liquors are percolating, a current of air is at the same time caused to pass through the interstices between the pieces of coke, by connecting the upper part of the tower with a chimney. By this arrangement an immense number of surfaces moistened with the liquors is presented to the current of air drawn through the tower, and the absorption of oxygen is thereby greatly facilitated. After passing through the tower, the liquors are collected in a pan to which heat is applied, and are afterwards pumped up, and caused to flow again through the tower. These operations are repeated until the sulphide of sodium in the liquors has become completely oxidised. The sulphide of iron, now in an insoluble form, is to be separated from the liquors either by subsidence or filtration; and the menstrua being rendered perfectly colorless, are freed from all iron, except such as exists as ferrocyanide of sodium. When the black-ash liquors are to be used for the production of soda crystals, or of soda ash, the conversion of the caustic soda present into carbonate of soda, is, by a modification of the process, effected collaterally with the separation of the sulphide of iron. All that is necessary for this purpose is to cause carbonic acid gas to pass through the tower with the atmospheric air. The liquors so purified are to be concentrated by the usual method employed in the preparation of soda crystals, or so as to obtain salts therefrom. In the further treatment of these salts and the residual liquor, and also the salts obtained in a similar manner by evaporating the mother liquor from soda crystals, the second part of Mr. GOSSAGE'S purifying process, namely, the separation of ferrocyanide of sodium, comes into operation. The first portions of the salts so deposited are but little impregnated with ferrocyanide of sodium; the second portions contain more of this compound; and the last portions are strongly impregnated with ferrocyanide, whilst the mother liquors still remaining contain a large proportion of this salt in solution. To separate it from these salts, they are to be washed with water or a solution of carbonate of soda.

For this purpose a series of four vats is employed, and the process is conducted exactly as in the lixiviation of black ash. In this mode of washing, the salts contained in each vat successively become those

least impregnated with ferrocyanide, and are subjected to the first action of the water, or of the washing solution. The solutions obtained by such washings are mixed with the mother liquors of the salts; and if it be found by testing that the mixed liquors contain more than ten parts of carbonate of soda for each part of ferrocyanide of sodium present, they are to be concentrated so as to obtain a further quantity of salts therefrom; and this concentration and separation of salts is to be continued, as long as the proportion of ferrocyanide of sodium to the carbonate of soda is less than ten per cent. The salts obtained by this last concentration are to be introduced into the concentrating apparatus with fresh black-ash liquor. The liquors above referred to as containing ten per cent. less of carbonate of soda for each one part of ferrocyanide, are collected and mixed with sufficient water and caustic lime to convert the carbonate of soda present into caustic soda, and the solution so obtained is to be concentrated until the greater part of the ferrocyanide becomes separated as salt; or the separation of the ferrocyanide may be effected by allowing the concentrated solution to crystallize; or, instead of converting the carbonate of soda contained in the liquors into caustic soda, the solution may be impregnated with carbonic acid, when bicarbonate of soda, a compound of sparing solubility, will be formed, and the greater part of the ferrocyanide may be obtained by filtration of water through the same, and drainage. The solution of ferrocyanide now contains only a small proportion of soda, which is converted by means of lime into caustic soda, and from this the ferrocyanide is separated either as salts or by crystallization. By resolution in water and repeated crystallization, the ferrocyanide is obtained sufficiently pure to be suitable for use.

Mr. GOSSAGE'S patent further includes a process for the production of caustic soda in a marketable state, in addition to white soda ash and ferrocyanide of sodium from black-ash liquors. In this operation, also, the liquors are first submitted to the oxidising action of atmospheric air as already directed. Any hyposulphate of soda contained in the purified liquors is then converted into sulphite or sulphate of soda by further oxidation; and this is effected by the gradual addition of solution of chloroxide of calcium, or bleaching powder. The liquors are now concentrated by the ordinary method so as to obtain salts therefrom; and these are washed as before described, to separate all the caustic soda and ferrocyanide of sodium. The mixed mother liquors and washings are then again concentrated, until the whole or nearly the whole of the carbonate of soda and ferrocyanide of sodium have become deposited as salts, and the solution or mother liquor remaining contains scarcely any saline matter but caustic soda. In this state it is suitable for many purposes to which caustic soda is applicable, and is a marketable product. The mixture of carbonate of soda and ferrocyanide of sodium in the form of salts, is washed with water by filtration; and the residue and washings are further treated exactly as before directed, for the preparation therefrom of pure soda ash and of ferrocyanide of sodium. By further concentration of the solution of caustic soda in cast-iron pans, it may be

so far deprived of water as to become solid hydrate of soda when allowed to cool, and in this state it presents great facilities for transportation.

At a later date, namely in 1857, Mr. GOSSAGE patented another invention, the object of which is to obtain an increased proportionate quantity of caustic soda or caustic potassa, or of carbonate of soda or carbonate of potassa, in the usual manufacture of soda or potassa. In the case of soda, this is effected, firstly, by using an increased proportionate quantity of small coal in the mixture employed, when decomposing sulphate of soda by fluxing. The proportions of these usually employed are three parts of sulphate of soda, three parts of carbonate of lime, and one and a half or two parts of small coal; but Mr. GOSSAGE uses nearly equal weights of each of these materials, reserving some part of the small coal to be added as the decomposition proceeds. The decomposition of some part of the carbonate of soda produced is alleged to be effected in this way, and an increased proportionate quantity of caustic soda is obtained when the fluxed mass is lixiviated. It would appear, however, from what has been stated regarding the composition of black ash, that an increased ratio of the calcareous substance would be much more effectual.

The second part of the process consists in the addition to the solutions obtained, of hydrated oxide of iron, of zinc, of manganese, or of lead, whereby the sulphide of sodium present is converted into caustic soda, with simultaneous production of sulphide of the metal employed. The decomposition is effected by adding to the solution obtained by lixiviation at a boiling heat, such a quantity of the metallic oxide as is found, by testing the solution with a salt of lead, to be sufficient to remove the sulphur from the whole of the alkaline sulphide present. The metallic sulphide thus produced, after being washed with water, is decomposed by means of muriatic or some other suitable acid, and the metal is obtained in solution. This, decomposed by means of hydrate of lime or magnesia, yields the hydrated metallic oxide in a condition applicable to the decomposition of a further quantity of alkaline sulphide.

To obtain an increased proportionate quantity of carbonate of soda, instead of caustic soda, in the process of manufacture, the alkaline sulphide is to be decomposed by the addition of the carbonate of iron, zinc, magnesia, or lead, and the metallic sulphide produced is reconverted to the state of carbonate by the addition to the solution of the metal obtained, as before directed, of carbonate of lime or of magnesia. This process, it should be observed, is one of a series of improvements in the manufacture of soda patented by Mr. GOSSAGE at the same time.

The primary object of these improvements is to render again available in the manufacture the sulphur contained in alkaline waste, which in the ordinary method is totally lost. As these relate more especially to the economical production of sulphuric acid, they will be further noticed in connection with the article to be specially devoted to that substance.

A process for impregnating black ash and white ash with carbonic acid, in order to convert the caustic and silicate of soda contained therein into carbonate, was

patented some years ago by Mr. JAMES SHANKS. In applying this process to black ash, the latter is to be broken into fragments and disposed in several layers, each of three or four inches in depth, in a stone or iron vessel named the *carbonator*. The layers having been moistened with water, carbonic acid gas is admitted into the carbonator by a pipe, the air being allowed to escape by another one. When the odor of sulphide of hydrogen is strongly perceptible at the exit pipe, the whole of the soda is considered to be carbonated; the introduction of carbonic acid is then discontinued, and the black ash is removed to the vats and lixiviated in the ordinary manner. The lie prepared from black ash may be exposed to the action of carbonic acid instead of the ash. In this case the carbonator used should have a capacity of sixteen cubic feet for every ton of white ash, or six cubic feet for every ton of soda crystals, to be made daily. Across the bottom of the carbonator is thrown an open arch of brickwork, and the space above is filled with small pebbles, over which the solution to be carbonated flows, being admitted at the top. The carbonic acid is introduced below the arch, and allowed to rise in the carbonator between the pebbles, the air of the vessel escaping by a pipe at the top. The greenish-yellow or brown color of the liquor disappears when properly carbonated.

With the same object in view, Mr. JOHN WILSON obtained a patent in 1840 for a process in which the caustic soda contained in either black or white ash is converted into carbonate by the application of as much bicarbonate of soda as might be necessary.

The entire loss of all the sulphur consumed as sulphuric acid in LEBLANC'S method of converting common salt into carbonate of soda, is justly considered a great objection to that process. Still, although numerous suggestions have been made, none of the new processes have succeeded so well as to supersede LEBLANC'S method; and the Editor is of opinion that it never will be supplanted. At the same time some of the plans recommended are so interesting in a purely theoretical point of view, that the Editor would scarcely be justified in omitting all notice of them.

One of the most economical of these processes is that proposed by Messrs. HEMMING and DYER, which is founded on the behavior of a solution of common salt with one of bicarbonate of ammonia. When carbonate of ammonia of commerce, which is in reality a mixture of carbonate and bicarbonate, is added in a state of fine powder to a solution of about an equal weight of salt in three parts of water, the mixture being well stirred, a white crystalline precipitate appears in a few hours, causing the liquid to become thick. This precipitate is bicarbonate of soda, and there is contained in solution chloride of ammonium, produced as shown in the annexed equation:—

In the manufacturing process founded on this reaction, common salt is mixed with an impure carbonate

of ammonia, such as the liquor furnished by the purification of coal gas, or the distillation of bones; and, having separated the solid bicarbonate by pressure in a screw press, the chloride of ammonium remaining in the mother liquor is reconverted into bicarbonate of ammonia, by evaporating it to dryness, and treating the residue in a distillatory apparatus with carbonate of lime, as in the ordinary mode of preparing carbonate of ammonia. The advantage gained by this process is the production of soda without the use of sulphur, and therefore free from this element; the objection to it is the loss of ammonia, and also that the portion of chloride of ammonium necessarily remaining with the bicarbonate of soda, is in the heat *reconverted* into the cheap chloride of sodium. In referring to this method, PARNELL observes, that unless particular precautions be adopted, the loss of ammonia must be very great and inevitable, from two reasons:—First, when a mixture of chloride of ammonium and carbonate of lime is heated, a portion of the ammonia is always disengaged in the free state, the product not being a neutral carbonate, but a sesquicarbonate, having the formula $2\text{NH}_4\text{O}, 3\text{CO}_2$. In this process, therefore, one equivalent of ammonia in every three is disengaged in the free state and lost, unless particular means be adopted to retain it. Again, when the sesquicarbonate of ammonia is dissolved in water, it is resolved into the neutral carbonate and the bicarbonate; but chloride of sodium is decomposed by the bicarbonate only, and the neutral carbonate remaining in the mother liquor is decomposed during the evaporation into free ammonia and the bicarbonate, both of which are volatilized. The adoption of some patented improvements in the manufacture of carbonate of ammonia, in which the mixture of chloride of ammonium and carbonate of lime is impregnated with as much carbonic acid as it will absorb, whereby the sesquicarbonate of ammonia is wholly converted into bicarbonate, would also be a decided improvement on the preceding process of manufacture.

Other processes have been proposed for producing carbonate of soda directly or indirectly from common salt, and some of these were even known and practised before the discovery of LEBLANC'S method. Thus, in 1788, a French priest named MALHUBE proposed a process which was afterwards put in operation by ALBAN, and was practised in France during the Revolution. In this, one hundred parts of sulphate of soda are first reduced to sulphide of sodium by heating to redness with twenty parts of charcoal; and while the mixture is in the liquid state, twenty parts of iron turnings are added, then eight parts of charcoal or small coal, next twelve and a half parts of iron, and lastly three parts of charcoal. The caustic soda thus obtained is exposed to the air, to absorb carbonic acid. DUMAS considers it probable, that in this operation there is formed a double sulphide of sodium and iron, and that the sodium converted into caustic soda is not more than half that contained in the fluxed product. In another process, sulphate of soda is reduced to sulphide of sodium by heating it to redness with charcoal, and having dissolved the sulphide in water, carbonic acid is passed through the solution till sulphide of hydrogen

ceases to be evolved. The carbonic acid is produced by burning charcoal or coke, or by calcination of limestone. According to DUMAS, to decompose sulphide of sodium by carbonic acid it is indispensable to use a considerable excess of the latter, so as to produce the bicarbonate of soda. Mr. GOSSAGE, however, states that he has succeeded in effecting the decomposition with such a proportion of carbonic acid as to produce the ordinary monocarbonate of soda. MARGRAAF suggested that carbonate of soda might be produced from the sulphide, by first converting the latter into acetate of soda by means of pyroligneous acid. When this is heated to redness, a residue remains, consisting of carbonate of soda and charcoal. LAMPADIUS proposed to form the acetate of soda by the addition to a solution of sulphate of soda, of one of acetate of lime, when insoluble sulphate of lime and acetate of soda are formed:—

KÖBUNTER proposes to form carbonate of soda by decomposing sulphate of soda with carbonate of baryta:—

and KNAPP suggests that in districts where potassa is obtained at a moderate price, the production of salt-petre may be combined with that of soda, by decomposing Chili salt-petre—nitrate of soda—and carbonate of potassa into soda and ordinary salt-petre:—

In treating of caustic soda, several methods for producing that salt, both from chloride of sodium and other salts of soda, have been detailed. These have also been applied in the manufacture of carbonate of soda, the caustic having been subsequently combined with carbonic acid, either by exposure to the air, or by heating it with coal or sawdust, or in some other way. In the patent of Mr. JOHN WILSON for improvements in the manufacture of carbonate of soda, already quoted, there is included a mode of preparing carbonate of soda from sulphide of sodium. He effects the conversion by mixing a solution of the sulphide with one of the bicarbonates, in the proportion of forty-eight parts of the former to eighty-five of the latter salt. The change is shown in the annexed formula:—

If the sulphide of hydrogen gas thus disengaged is to be collected, the materials may be mixed in a covered

iron pan, furnished with a pipe to conduct the gas to a gas-holder; but if the gas is not required the operation may be carried on in a common white-ash furnace. The mixture is evaporated to dryness, the residuary carbonate dissolved in water, and the clear solution is decanted and re-evaporated.

The soda process proposed and patented by MM. BLANC and BAZILLE, differs from nearly all the above-mentioned, inasmuch as the use of sulphur for the production of either sulphate of soda or sulphide of sodium is totally dispensed with. This method is founded on the decomposition of common salt by silica at a high temperature, and in the presence of steam. When the vapor of water is passed through an intimate mixture of common salt and silicious sand, contained in a porcelain tube heated to bright redness, the salt is decomposed, the chlorine unites with the hydrogen of the steam to form hydrochloric acid, which escapes as gas, while the sodium combines with the oxygen of the steam and with the silica or silicic acid, to form silicate of soda. The annexed equation represents the change:—

The decomposition, it will be observed, cannot take place unless water be present. In carrying out this process on a manufacturing scale, the patentees propose to introduce the mixture of salt and silicious sand into cast-iron cylinders, arranged in furnaces in a manner similar to gas retorts, so that the flame may play around and raise them to a cherry-red heat. A large perforated tube for the introduction of steam, as long as the cylinder, is to traverse the axis of each cylinder; and at one extremity of the cylinder the tubes must be each fitted to a large earthen or stone-ware tube for the purpose of conducting the evolved hydrochloric acid to the condensers. The latter tube should be of considerable size, to prevent its being choked up with volatilized salt; and it should lead first into a large empty chamber in which the volatilized salt might be deposited; a communication between this chamber and the condensers may afterwards be established.

The cylinders thus arranged are to be loosely filled with an intimate mixture of twenty-eight parts of salt and twenty parts of fine sand, and raised to a cherry-red heat; steam being at the same time slowly and steadily admitted into the perforated tube from a boiler.

To remove the undecomposed salt from the mass so obtained, it is to be lixiviated with water, in which the silicate is scarcely soluble; and to procure this in a state of solution, it is first calcined at a red heat with about one sixteenth of its weight of soda ash, until the mixture is vitrified. The subsilicate of soda thus formed is dissolved in water; and from the solution carbonate of soda may be obtained by impregnation with carbonic acid, which causes the precipitation of gelatinous silica; the soda salt remaining in solution. The patentees

prefer to procure the carbonic acid gas from the limestone by calcination in continuously acting limekilns. To the top of the kiln is adapted a dome-top, from which a tube passes into the vessel containing the solution to be carbonated; and it is alleged that the draught of the kiln is quite sufficient to maintain a proper degree of combustion to the end, if a single large vessel be employed to contain the solution instead of several small ones.

It is probable, as PARNELL remarks, that the manipulations required in these operations would be too tedious, and the decomposition of the salt in the cylinders too slow and incomplete, to allow of the process being prosecuted successfully on a large scale.

A plan was proposed by MAUGHAM for the production of silicate of soda, somewhat similar to the above, but with the additional aid of hydrofluoric acid. He then decomposes the silicate of soda by means of carbonate of lime.

SESQUICARBONATE OF SODA.—This salt exists as a natural product in solution in water. The mineral waters of Vichy and of Vals in France, of Bilin in Hungary, of Carlsbad in Bohemia, and the Geyser fountains in Iceland are remarkable examples. It is also produced as a mineral termed *trona* or *urao*, round the margin of some lakes in Northern Africa, Hungary, and South America. Its existence in nature is accounted for by some, on the supposition that chloride of sodium is decomposed by carbonate of lime, as BERTHOLLET observed that whenever these two salts were found mixed together there was also an efflorescence of sesquicarbonate of soda. DUMAS, however, dissents from this, and considers its formation to be owing to the decomposition of the sulphate of soda, which is always found in admixture with chloride of sodium. The sulphate of soda he supposes to be first reduced to sulphide of sodium by the action of organic matters in solution in the water; and the sulphide of sodium is afterwards converted into sesquicarbonate of soda by means of the carbonic acid also held in solution in the water of soda lakes. The lakes are usually called *white*, from the circumstance that, during the summer months, the water evaporating leaves a snow-white efflorescence on the surface at the bottom. This is sesquicarbonate of soda.

The plains on the shores of the Black and the Caspian Seas, Persia, Arabia, India, Thibet, China, and Siberia, and even the great desert of Africa—all furnish this variety of carbonate of soda.

This salt may be prepared artificially by several methods.

According to WINCKLER, if four ounces of alcohol be poured on the surface of a solution containing one hundred grains of simple carbonate of soda, and one hundred and fifty-two grains of crystallized bicarbonate of soda in four ounces of water; fine, clear, circular crystals of the sesquicarbonate are formed after several days at the surface of separation of the two liquids, and at the bottom of the solution large crystals of the simple carbonate are formed, together with a crust of bicarbonate of soda.

According to HUMANN, sesquicarbonate of soda

cannot be prepared pure by crystallization from any aqueous solution, as it decomposes when in solution into the bicarbonate and carbonate of soda, which crystallize apart. When a concentrated solution of the bicarbonate is evaporated quickly, so as to avoid the dissipation of the whole of the second equivalent of carbonic acid; when the bicarbonate and crystallized carbonate are mixed in single equivalent proportions, and the mixture is caused to undergo the watery fusion; and, lastly, when the bicarbonate of soda is exposed to heat, the temperature not being allowed to exceed 482° , products are obtained, which consist for the most part of sesquicarbonate. If these masses are exposed for a few weeks to a humid atmosphere, they assume a perfectly crystallized structure; and their cavities and fissures become lined with groups of crystals, which are pure sesquicarbonate of soda. The form of the crystal of this salt is that of the rhombohedral prism, terminated by quadrangular pyramids. It dissolves in water more readily than the bicarbonate, but less easily than the simple salt, and the solution possesses an alkaline reaction. It is unalterable in the air, a remarkable proof of which is given by DUMAS, who asserts that the walls of Cassar, a fort in Africa actually in ruins, have been constructed with natural masses of this salt, originally obtained from some of the native lakes which abound in the country. It was formerly imported into this country, and sold under the name of *tronse*, and hence probably originated the error of the London college in substituting the sesquicarbonate for the bicarbonate of soda.

BICARBONATE OF SODA.—This salt may be obtained by passing carbonic acid through a concentrated solution of the simple carbonate; but the process is tedious and attended with much waste of gas, unless pressure be employed. Some manufacturers economize carbonic acid, by exposing the solution for a long period in shallow vessels to the atmosphere of a fermenting vat. In both cases bicarbonate of soda separates after some time in minute grains, owing to its comparatively sparing solubility; and the mother liquor, by cautious concentration at a temperature not exceeding 120° , yields a further quantity. In the process of SCHÖFFER, from three to four parts of crystallized carbonate are intimately mixed with one part of commercial sesquicarbonate of ammonia; the semifluid mass thus obtained, which evolves ammonia, is allowed to stand twenty-four hours, and then exposed to the sun on a clear surface. The last trace of ammonia escapes with the water, and bicarbonate of soda remains as a chalky mass. As the ammonia evolved in this method is lost, and as it is difficult to evolve in close vessels, SCHORZ proposed to mix fifty parts of dry carbonate of soda in fine powder with fifteen parts of the crystallized carbonate and forty-one parts of carbonate of ammonia, and to heat the mixture in a distilling vessel immersed in water.

The first nine-twelfths of the ammonia are readily evolved; the second two-twelfths with greater difficulty; and the last one-twelfth is removed by exposing the mass to the air. Manufacturers on the large scale have generally abandoned all the liquid processes for producing bicarbonate of soda, in favor of the dry

way; and this is certainly preferable both as regards economy, convenience, and despatch.

The process commonly followed is that suggested by SCHÖFFER, and introduced into the Parisian codex of 1840. It consists in packing fragments of crystallized carbonate of soda upon a series of perforated shelves in a box, or in large air-tight iron cisterns without shelves, but with an airhole at the side, and a small pipe at the bottom to carry off the water of crystallization, which separates during the process. After the introduction of the salt, carbonic acid is admitted in a stream regulated according to the rate of its absorption. The carbonic acid may be derived by the decomposition of chalk or limestone by hydrochloric acid, or, with proper precautions, from a charcoal or coke fire, or from a liquor undergoing the vinous fermentation. The latter method may be advantageously practised in distilleries, where a great quantity of liquor is kept in a fermenting state for a considerable time.

As carried on in alkali works, the first method is the one usually practised; the muriatic acid obtained in the production of sulphate of soda being made to act upon chalk or limestone.

The evolution apparatus employed consists of a large stone cistern laid in clay and well bedded. It is provided with a pipe, continued to within a few inches of the bottom of the cistern, and through this the acid is admitted from the condensers. The cistern being filled with chalk, the acid is allowed to flow in, and, rising through the mineral, it disengages carbonic acid in the passage; and the solution of chloride of calcium formed escapes through another pipe, similar to that by which the acid is admitted. The escaping liquors flow off through a third pipe, and the carbonic acid issues through an opening, whence it is conducted to the cisterns or boxes containing the crystallized carbonate of soda. The gas coming in contact with the crystals is very rapidly absorbed; and at the same time a liquid, charged with carbonate of soda or sesquicarbonate, trickles down to the bottom of the cistern, owing to the carbonate containing more water of crystallization than is required to constitute the bicarbonate. This liquid is usually withdrawn from time to time, as may be necessary. During the absorption of the gas a considerable amount of heat is evolved; and at the end of ten days or a fortnight the whole is converted into bicarbonate of soda, which is, however, very damp. This moisture is removed by heating the mass in stoves fitted with wooden shelving, by air passed through hot iron pipes.

A great improvement on this method in small operations, and which has also been adopted on the large scale, is the process suggested in its details by MOHR. In this method, the crystallized and anhydrous carbonates are mixed in such proportions as to leave a slight excess of water over what is necessary for the water of crystallization of the whole salt, when it is converted entirely into bicarbonate; and carbonic acid is admitted to the bottom of the mixture by a tube proceeding from a pneumatic apparatus similar to a gasometer, so constructed that there can never be any waste of gas. The absorption is completed every twenty-four hours.

MOHR proposed to mix anhydrous carbonate so as to leave no excess of water over that required for the water of crystallization of the bicarbonate. CHRISTISON, however, who carefully investigated the subject, found that absorption does not take place at all with the proportions proposed by MOHR; that with nothing but crystallized carbonate the absorption is slow, and the disengaged water contains carbonate or sesquicarbonate; but that with such proportions of the crystallized and anhydrous carbonates as will leave a slight excess of water, absorption is prompt, a slightly damp salt results, and there is not an appreciable quantity present of any other carbonate besides the bicarbonate.

The rapidity with which effloresced carbonate of soda, or what is practically the same, a mixture of crystallized and anhydrous carbonate, absorbs carbonic acid, is stated by ARTUS to be considerably increased by mixing with the salt recently calcined and powdered charcoal, made from soft wood, which possesses the power of condensing gases within its pores to an extraordinary extent. When it is desired to obtain the bicarbonate in crystals, advantage may be taken of this property of charcoal. The mixture, which may be made in the proportion of two parts of effloresced carbonate and one part of charcoal, is moistened and exposed to the gas for twenty-four hours, then taken out, powdered, and moistened, and again exposed to the gas. These operations having been twice repeated, the mass is mixed with eight parts of hot water; the solution is filtered while hot, and left for the bicarbonate to crystallize. Carbonate of soda is known to be fully saturated with carbonic acid when it no longer reddens turmeric, or gives a precipitate with a very dilute solution of chloride of mercury or corrosive sublimate, but with a concentrated solution a white precipitate, which becomes red in a few minutes, and afterwards purple; with the least admixture of simple carbonate of sesquicarbonate of soda, the precipitate is reddish-brown.

Bicarbonate of soda is known only in combination with water, its formula being— $\text{Na O}, 2 \text{ CO}_2, \text{HO}$. It crystallizes in oblique four-sided tables, which have a slightly alkaline taste and a very feeble alkaline reaction on vegetal colors. As met with in commerce, it is usually in the form of powder, or in small, white, opaque, irregular scales. At a moderate heat, it loses half its carbonic acid and the whole of its water, and is reduced to the state of anhydrous monocarbonate. Cold water dissolves about one-tenth of its weight, and hot water considerably more. When the solution is heated somewhat above 120° , carbonic acid begins to be eliminated; and, according to BERZELIUS, at 212° the salt becomes sesquicarbonate.

Physiological Effects.—Bicarbonate of soda possesses diuretic properties, but less actively than the corresponding salt of potassa. It is also an excellent antacid and antilithic, and is employed in great quantity for making effervescent powders. A mixture of this salt with the tartrate of soda and potassa, or Rochelle salt, with the addition of tartaric acid, constitute seidlitz powders. Many have thought that the long-continued use of alkaline carbonates in gravel and acidity of the stomach entails injurious consequences; and diseases of the kidneys as well as organic disorders of the

stomach have been referred to the practice. These suppositions are probably imaginary, as there can be no question that many have employed alkaline remedies habitually for years, without apparently any deleterious effects being produced; the Editor can affirm this from his own experience.

HYPOCHLORITE OF SODA—CHLORIDE OF SODA—CHLOROXIDE OF SODIUM.—A solution of this salt in an impure state constitutes the well-known disinfectant liquor of LABARRAQUE. Its disinfecting power was discovered about the year 1820. The process for preparing this solution given in the London Pharmacopoeia is as follows:—A pound of crystallized carbonate of soda is dissolved in two parts of water, and the chlorine eliminated by heating a mixture of four ounces of common salt, three ounces of binoxide of manganese, four of sulphuric acid, and three of water, is conducted into the solution. The changes that ensue are represented in the subjoined formula, the result of the decomposition being a mixture of bicarbonate of soda, hypochlorite of soda, and chloride of sodium:—

The above is the method followed in the preparation of this salt by LABARRAQUE; PAYEN proposed another, which was adopted by the French pharmacists. It consists in the decomposition of chloroxide of calcium, or bleaching powder, by carbonate of soda. The proportions employed are one part of bleaching powder and thirty of water, and for the carbonate of soda solution two parts of the crystallized carbonate and fifteen of water. In this process hypochlorite of soda and chloride of sodium are formed, and remain in solution whilst carbonate of lime is precipitated. By using the proportion of the French Codex, the solution obtained is much weaker than that prepared as directed by the London College. Pure hypochlorite of soda can only be obtained by neutralizing a solution of hypochlorous acid with one of soda.

LABARRAQUE'S disinfecting compound may be obtained in the solid state, according to MAYER and SCHINDLER, by transmitting chlorine, evolved from ten parts of common salt, eight parts of binoxide of manganese, and fourteen parts of sulphuric acid, into nineteen parts of dry powdered carbonate of soda, moistened with one part of water only. The absorption of chlorine goes on slowly with the disengagement of heat.

Properties.—The solution known as LABARRAQUE'S disinfecting fluid is colorless or slightly yellow, has an odor of chlorine and an astringent taste. Upon vegetal coloring matter it first reacts as an alkali, and afterwards effects its destruction. By evaporation needle-shaped crystals are obtained, which when redissolved in water reproduce the bleaching fluid. Acids added to the solution disengage chlorine and carbonic acid gas, and by exposure to the air decomposition is also effected, and crystals of carbonate of soda are formed.

Physiological Effects.—This salt, as well as the soluble hypochlorites, is supposed to exercise a specific

influence over the nervous system, causing depression and tetanus. In small doses it has been considered to possess tonic, alterative, and febrifuge properties, and has, consequently, been proposed as a remedy in strumous diseases, chronic affections of the liver, ague, and the typhoid form of continued fever. Its utility as an external remedy is, however, much better established than its alleged therapeutic properties as an internal agent. When considerably diluted it is an excellent stimulant for ill-conditioned sores on the surface of the body, and especially for promoting cicatrization.—*Christison*,

According to PEREIRA it is most valuable as a disinfectant antiseptic, and as an antidote in cases of poisoning by the sulphides and by hydrocyanic acid; and he remarks, that in several cases where he had carefully compared it with chloroxide of calcium he gave the decided preference to the chloroxide of sodium. LABARRAQUE recommends its employment as an antiseptic, on the ground that by the process of disinfection it becomes chloride of sodium, which is not a deliquescent salt, whereas the chloride of calcium existing in and generated by bleaching powder, attracts water from the atmosphere, and thereby furnishes one of the conditions necessary to the putrefactive process. Hence, in his opinion, while chloride of lime will serve equally well for mere disinfection, chloride of soda is preferable when one wishes at the same time to prevent a renewal of putrefaction.

HYPOSULPHITE OF SODA.—There are several modes of procuring this salt. It is very conveniently prepared by first forming a solution of neutral sulphite of soda, by passing sulphurous acid gas into a strong solution of the carbonate of this base. The sulphite so obtained is then digested with sulphuric acid for several days at a moderate heat. In this case sulphurous acid, by taking up sulphur, becomes hyposulphurous acid, thus—

Or a solution of soda may be first saturated with sulphur by boiling, and sulphurous acid may then be passed through this menstruum, when hyposulphite of soda is formed. In either case the solution obtained is rapidly evaporated to a sirupy consistence and then set to repose, when the hyposulphite separates in large colorless crystals.

A very convenient process for the production of this salt on the small scale is that recommended by WALCHNER. A pound of pure crystallized carbonate of soda is dried as perfectly as possible, and then intimately mixed with five ounces of pure sulphur; the mixture is gradually heated in a glass or porcelain basin to the melting point of the sulphur, and kept at that temperature for some time, stirring constantly in order to bring every part in contact with the air. The sulphide of sodium formed at first absorbs oxygen from the air, and is converted with feeble incandescence into hyposulphite of soda. The mass, when cold, is dissolved in water boiled with sulphur for some time, and the filtrate is evaporated, when very fine and pure crystals separate. If the heat employed be too strong, part of

the sulphur is burned off, and carbonate of soda remains undecomposed. In this case a second crystallization is necessary.

Properties.—Crystallized hyposulphite of soda— $\text{Na O, S}_2\text{O}_2, 5\text{HO}$ —is an inodorous salt with a taste first cooling, and afterwards bitter. The crystals are oblique prisms, belonging to the right prismatic system. They are deliquescent in the air, but *in vacuo* lose their water of crystallization. When heated, the salt at first undergoes the aqueous fusion, and then dries up into a white mass; the heat being continued, it takes fire, burning vividly and with a clear yellow flame. Hyposulphite of soda is readily soluble in water, but not in alcohol. In close vessels the aqueous solution deposits sulphur till nothing but sulphite of soda remains in the liquid; exposed to the air it deposits sulphur, and the sulphite is converted into sulphate of soda.

Hyposulphite of soda, and other soluble salts of hyposulphurous acid, possess the remarkable property of dissolving all the compounds of silver, even the chloride, and the solution thus formed has a very intense sweet taste, with a metallic after-taste. This property has been made available in the daguerreotype, for the purpose of dissolving the sensitive coating of iodide from the plate of silver after exposure to light, and thus fixing the image already formed. For this purpose hyposulphite of soda is now prepared on a very considerable scale.

ANALYSIS.—The compounds of sodium may be distinguished from all other salts in a most unmistakable manner, though the tests are almost of a purely negative character. In the pure state, the mode of recognition is as follows:—When dissolved in water, no precipitate or other change is produced by the addition of hydrochloric acid, sulphide of hydrogen, sulphide of ammonium, carbonate of ammonia, or bichloride of platinum; but if the solution be evaporated to dryness, or if a little of the original substance be taken and exposed on a platinum wire to the inner flame of the blowpipe, the outer flame becomes of an intense yellow color, owing to the reduction of the soda and the subsequent oxidation of the reduced sodium.

This test is a safe, and mostly in itself sufficient proof of the presence of soda, provided always a fixed alkali alone be present and in the form of chlorides; the one hundredth part of soda may by this means be detected in presence of potassa. A precipitant has been proposed for soda, which is not, however, of any great value, and is very rarely employed; this is the antimoniate of potassa. It produces, in neutral or alkaline solutions of salts of soda, a white crystalline precipitate of antimoniate of soda, which in concentrated solutions is formed immediately, but in dilute solutions, only after the lapse of some time. Its formation is promoted by vigorous shaking of the mixture. This test gives decisive results only when applied with a careful and attentive consideration of the attendant circumstances. The most indispensable condition of its applicability is, that besides soda and potassa, no other bases must be present in the solution, since the salts of the heavy metallic oxides, those of the earths proper, and of the alkaline earths, and finally those of ammonia, are also

thrown down by antimoniate of potassa. The solutions, too, must be neutral or alkaline, since otherwise the reagent suffers decomposition, and hydrated antimonie acid or acid antimoniate of potassa is precipitated from it. Soda is usually estimated quantitatively as sulphate of soda or as chloride of sodium.

Other compounds of soda are converted into sulphate by adding to their aqueous solution a quantity of sulphuric acid more than sufficient to saturate the whole of the soda; the solution is then evaporated to dryness, and the excess of sulphuric acid expelled by ignition, adding now and then a portion of carbonate of ammonia.

Every one hundred parts of sulphate of soda so obtained represent 43·66 of soda. Of chloride of sodium obtained in a similar manner, one hundred parts represent 39·34 of sodium, or 53·02 of soda. Salts of soda are also sometimes determined as carbonate of soda; and for soda salts with organic acids this method is preferable to all others.

Caustic soda is converted into carbonate by adding to its aqueous solution carbonate of ammonia in excess, evaporating at a gentle heat, and igniting the residue. The bicarbonate of soda is converted into the simple carbonate by ignition; and the salts of soda with organic acids are converted into the carbonate by heating gradually in a covered crucible, the charcoal being afterwards removed by igniting the residue in a gentle current of air. Every one hundred parts of carbonate of soda obtained represent 58·49 of soda.

Lastly, the determination of the commercial value of

some soda compounds, as soda ash, caustic soda, borax, *et cetera*, is effected by noticing the quantity of acid of known strength required to neutralize a given weight of the salt. The process recommended by Mr. FARADAY is as follows:—Into a tube of about three-quarters of an inch in diameter, and nine and a half long, and as cylindrical as possible throughout its whole length, one thousand grains of water are to be weighed, and the space occupied marked on the tube with a fine file; this space is then divided from above downwards into one hundred equal parts. At 23·44 or 76·56 parts from the bottom an extra line should be made, and soda marked opposite to it; at 48·96 potassa should be marked in the same way; at 54·63 carbonate of soda; at 65 carbonate of potassa. A diluted acid is now to be prepared, which shall have a specific gravity 1·127, and this is made by mixing intimately together nineteen parts by weight of oil of vitriol and eighty-one of water. The method to be followed in the employment of this acid is as follows:—The dilute acid is to be measured in the tube up to the line opposite to which the alkali sought for is marked; if barilla, which contains carbonate of soda, 54·63 measures are to be taken. The one hundred measures are then made up by the addition of water, and is then ready for use. But these processes, which constitute a very important branch of commercial analysis, have been fully discussed under *Alkalimetry* in connection with the article POTASSA, Vol. II., page 729 *et seq.*, to which the reader is referred for details.

STATISTICAL REPORTS OF THE ALKALI TRADE OF THE UNITED KINGDOM FOR THE YEAR 1852, DRAWN UP BY
J. WILLIAMSON, ESQ., JARROW CHEMICAL COMPANY, SOUTH SHIELDS,

From full returns by sixteen manufacturers, representing 46% of the trade.
From partial returns by eleven manufacturers, representing 35% “
No returns by sundry manufacturers, representing 19% “

Amount contributed by the alkali trade to the annual income of this country,.....£1,063,460.

This report is the only accurate return ever made of the alkali trade. The manufacture in Lancashire has, however, greatly increased of late years; but if the total amount given be doubled, the figures will represent pretty nearly the present yield of the manufacture.

STARCH.—*Amidon*, French; *Sterke*, German; *Amylum*, Latin.—Starch exhibits to the naked eye the appearance of a white glistening powder, which, under a higher visual power, is found to be composed of a number of very minute, colorless, and semitransparent grains. It is a secretion educed from most plants and seeds, though contained in some in much greater proportion than in others; and it would appear that its end is to produce cellular structure under the vital power of the plant, as well as to give support to the embryo seed till it is able to gather sustenance from extraneous sources.

HISTORY AND SOURCES.—This substance has long been known: the ancient Greeks called it *αμυλον*, from the circumstance of its not being prepared by grinding in mills like other farinaceous matters. PLINY attributes to the inhabitants of the island of Chio the discovery of the method of extracting it from wheat flour. Very little is said concerning it in any historical work down to modern times. FOSBROKE states that starches of various colors were imported into England from Holland in 1564—that which was yellow being esteemed the best for ruffs and other articles.

The starches more commonly known as products of particular seeds or parts of plants, are in a measure restricted to a definite number of organic productions, which secrete them for the purposes already alluded to; but if by starch be meant the analogues of this substance, having the same or a closely allied composition, then it may be said to form a constituent of all plants at one stage or another of their existence. The fact that starch of one form or other enters at some particular period into the composition of plants, is the more certain from the consideration of the variety of starches and their congeners. Of these there are three kinds known, namely, *common starch*—such as is extracted from the monocotyledonous and bicotyledonous seeds, and from several roots, tubers, *et cetera*—also *lichen starch*, and *inulin*. The first is the primary link between cellulose and dextrin or artificial gum; the second is intermediate between cellulose and dextrin; and inulin is the connecting link between common starch and sugar. On examining the transformations which the seeds of many plants, such as the cereals, the tubers, or leguminous plants—seeds which are rich in starch—undergo when germinating, it is evident that they effect the solution of the substance of the amylaceous matter into gum, or dextrin, or sugar, whence the carbon necessary for the increase of the young germ is extracted; and so likewise the starch which is abundant at one period of the growth of plants, but which at a more advanced stage disappears, must have passed through an analogous modification necessary for the development of another secretion. This department of vegetal physiology is, however, not sufficiently investigated to admit of explaining with certainty the intermediate stages of the secretion and decomposition of the starch granules in plants; but the fact that starch appears at one period of the growth of a plant or the formation of a fruit, and disappears at another, warrants the supposition that where sugar or gum is discovered, starch, organized in the form of granules or in some other

stages, has probably preceded these, or will result from them.

The term starch may be used here in a generic sense to designate the variety of organized structures educed from seeds, roots, and stems of plants belonging to different orders and families, in consequence of such educts offering marked analogies of properties and composition, though differing in physical characters. When it is requisite to distinguish the particular kinds, the source is mentioned; hence wheat, potato, arrow-root, sago, rice, and other starches. Wheat starch is generally called *amidon*, which term is applied not only to the amylaceous matter educed from wheat, but likewise to the similar products of the other seeds of the cerealia in the grains of the leguminosæ, the chenopodiaceæ, *et cetera*. Potato starch has its synonym in *fecula*, and this also is the term by which the starch from the carrot, beet, yam, and the like, are distinguished from the foregoing, as likewise arrow-root, sago, and other kinds. Arrow-root starch is found in the roots of many plants belonging to the family of *Scitamineæ zingiberaceæ* and *euphorbiaceæ*, as the *maranta arundinacea*, and *indica*, from which it is extracted in Jamaica; and the *curcuma angustifolia* from which it is prepared in the East Indies. Sago starch exists in the pith of the palm tribe, especially the *Sagus Rumphii*, *Cicasinermis*, *C. revoluta*, *Coryza urens*, *Borassus gomato*, and several species of *Zamia*, *Corypha*, and *Mauritia*, and can be extracted from them. Besides these, there is another variety of amylaceous secretion, which, differing from them in physical characteristics, is still allied to the preceding in chemical composition, and this is known as *inulin*. It is the immediate principle extracted from the roots of many plants, as the *dahlia*, *elecampane*, *inule*, *helenium*, *colchicum*, *dandelion*, *chicory*, *Iceland moss*, *Carrageen moss*, and several of the lichen and fucus tribe of plants. The latter is little used in the industrial arts of Europeans, though employed in China for the manufacture of transparent lamps and tablets similar to the gelatin articles of the French.

PHYSICAL PROPERTIES.—Particles of starch viewed under a high magnifying power, appear in well-defined grains, in most cases more or less oval; in others polygonal. Notwithstanding an evident analogy between starch particles, from whatever sources obtained, there still remains such difference in their shape and size as to enable any person acquainted with them to identify any particular species even when mixed with others from a different source. Size is the most important criterion, and PAYEN'S researches in measuring the relative magnitude of the starch granules from various sources, constitute perhaps the best guide for the student; hence the following measurements and engravings of the appearance of the various starches, from his *Chimie Industrielle*, will be found useful. The details are of forty-one varieties:—

Fig. 523.—*Fecula* of the *Canna gigantea* measure in length 175 thousandths of a millimetre—equal seven thousandths of an inch, the millimetre being 0·03937 of an inch; *a*, *b*, *c*, *d*, *e*, represent the normal starch granules; *f*, *f'*, *f''*, granules partly exfoliated by vegetation which wastes them. The grains of the

Columba roots—*Minispermum palmatum*—measure 180 thousandths of a millimetre, and those of the

Fig. 523.

Case 1.

large ripe potato—of Rohan—185 thousandths of a millimetre.

Case 2.—Fecula of the arrowroot of commerce—*Maranta arundinacea*—attains a length of 140 thou-

Fig. 524.

Case 2.

sandths of a millimetre; *a*, *b*, *c*, *d*, represent the normal external coating separated from the inclosed matter by pressure. Fecula from the bulb of the lily has the same dimensions.

Fig. 525.

Case 3.

Case 3.—Bean starch, the maximum length of which is 75 thousandths of a millimetre—three thou-

sandths of an inch. At *a a'*, *b b'*, *c c'*, *d d'*, the granules are seen in two positions, exhibiting length, breadth, and depth, and also the median canal impression.

Case 4.—Starch from the tubercles of the *Oxalis crenata*, 85 thousandths to 100 thousandths of a millimetre. Fecula from the largest *Echinocactus erinaceus* imported, 75 thousandths of a millimetre.

Cases 5 and 6.—Detached and agglomerated grains of the pith of the *Cycas circinalis*—sago—the length

Fig. 526.

Case 4.

Case 5.

Case 6.

of the largest of which measures 50 thousandths of a millimetre.

Case 7.—Wheat starch granules, *a*, *a'*, *a''*, in three positions, the largest of which are from 45 to 50 thousandths of a millimetre.

Case 8.—The same starch, the orifice or hilum of

Fig. 527.

Case 8.

Case 7.

which is rendered visible by heating to 396°, and examining the granules subsequently in alcohol of 0.85 specific gravity.

Case 9.—The same starch viewed after the evaporation of the alcohol, showing where the residual water has dissolved a portion of the exterior of the globule.

Fig. 528.

Case 9.

Case 10.

Case 10.—The same starch after the internal matter has been dissolved by an excess of water.

Case 11.—Fecula of the red sago of commerce, the grains of which are partly swollen and deformed by heat.

Case 12.—Fecula of white sago, showing the alterations suffered in the preparation by the effects of a high temperature and the presence of a large quantity of water; this variety, as also lentil starch, measures 75

Case 11.

Fig. 529.

Case 12.

Case 13.

thousandths of a millimetre; kidneybean or haricot starch 67 thousandths; and that of large peas 36 thousandths of a millimetre.

Case 13.—Indian corn starch. Here *a b, c d*, represent the grains encased and compressed in two contiguous cells of the horny part of the perisperm; *e, e, e* represent three compressed grains; *f, g*, detached grains, 25 to 30 thousandths of a millimetre.

Case 14.—Fecula of the bulb of the hyacinth, showing several double grains; the greatest length is 45 thousandths of a millimetre.

Fig. 530.

Case 14

Case 15.

Case 15.—The same, showing the exfoliation of the granules in an old shell.

Case 16.—Fecula of beet, showing several double grains and appearing conical; length 40 thousandths of a millimetre.

Case 17.—Shows the same heated to 360° to develop more plainly the hilum or aperture.

Case 18.—The same fecula as it appears at the commencement of its hydration after the evaporation of the alcohol.

Case 19.—Fecula of the *Orchis bifolia*, many granules of which have two apertures or hila, and double lateral conical protuberances.

Case 20.—Fecula of the *Orchis latifolia*, the grains of which are ovoidal, pear-shaped, *et cetera*, with a

Case 16.

Fig. 531.

Case 18.

Case 17.

Case 19.

double hilum. Both these kinds of starches measure 45 thousandths of a millimetre.

Case 21.—Starch grains found in the tubercle of the potato, the growth of which was arrested. The granules are seen forming two or more smaller corpuscles at the expense of the larger ones; also the more developed

Fig. 532.

Case 20.

Case 21.

Case 22.

grains, several of which are adhering two and two together, with a few grains acted upon with a solution of soda containing 0.005 of the caustic alkali, and swelling the matter in the interior so as to cause it to exude.

Case 22.—Fecula extracted from the stem of the *Cactus Peruvianus*, showing the single, double, and triple grains. It measures from 25 to 30 thousandths of a millimetre.

Case 23.—Represents the starch of the red sorgho, most of the grains of which exhibit a polygonal outline,

Fig. 533.

Case 23.

Case 24.

Case 25.

Case 26.

and measure 30 thousandths of a millimetre. The amylaceous organization of the *Cactus pereskia grandiflora* are of the same size, as also that of the *Naïas major*.

Case 24.—Starch grains of the *Aponogetum dis-*

tachyum of a truncated polygonal form; they measure 22 thousandths of a millimetre. Such also is the dimension of the starch contained in the stem of the *Ginkgo bilobi-saliburia adianthifolia*.

Case 25.—Exhibits the same swollen by a solution of soda.

Case 26.—Shows the starch of the *Cactus cereus grandiflora*, and which measures 20 thousandths of a millimetre.

Case 27.—Fecula of the *Cactus Braziliensis*, showing the double and triple grains; it measures 18 thousandths of a millimetre.

Case 28.—Starch of the *Panicum Italicum* in polygons; measures 16 thousandths of a millimetre.

Case 29.—Fecula of the *Cactus flagelliformis*, measures 15 thousandths of a millimetre. The pollen of the *Globba nutans* has the same dimension.

Case 30.—Starch of the *Echinocactus erinaceus*, measures 12 thousandths of a millimetre. Pollen of the *Rupia maritima* is 11 thousandths of a millimetre.

Case 31.—Starch of the *Cactus opuntia tuna* is 10

Fig. 534.

thousandths of a millimetre. The starch of the *Ficus indica*, as also that of the *Cactus curassavicus*, have the same dimensions.

Case 32.—Starch of the *Aylanthus glandulosa* measures 7 to 8 thousandths of a millimetre.

Fig. 535.

Case 33.—Represents the starch grains of the *Cactus curassavicus*.

Case 34.—Starch from the parsnip, measuring 7 thousandths of a millimetre.

Case 35.—Shows the granules of the *Ficus indica*.

Case 36.—Shows the double starch granules of the *Cactus serpentinus*, 7 thousandths of a millimetre.

Case 37.—Fecula of the *Cactus monstrosus*, measuring 6 thousandths of a millimetre.

Case 38.—Millet starch—*Panicum miliaceum*—exhibiting the polygonal form; they measure 9 thou-

sandths of a millimetre. The inclosed grains are those that have been swollen with a solution of soda.

Fig. 536.

Case 37. Case 38. Case 39. Case 40. Case 41.

Case 39.—Starch of the *Cactus mamillaria discolor* exhibiting several double grains; length 8 thousandths of a millimetre.

Case 40.—Starch grains of the sugar beet, exhibiting a globular form; the largest measure 4 thousandths of a millimetre.

Case 41.—Starch from *Chenopodium quinoa*, of rounded form, measuring only 2 thousandths of a millimetre.

Thus it will be seen, that the most general forms of starch corpuscles are ovoidal, conical, and polygonal; the first and second shapes prevail when the cellular structure, in which the granules are inclosed, offers sufficient space and retains as much moisture as to confer elasticity upon the coats and interior substance of the grain; but sometimes the granules are collected in large numbers in the cells of the seed or plant, which in turn are closely bedded in the *testa* or outer covering; in such cases—as shown in Case 13 in preceding plate—the compression causes the walls of the amylaceous bodies to assume polygonal forms.

SCHLEIDEN and others describe the formation of a starch corpuscle as commencing from a spheroidal granule, the nature of which is assumed to be different from the matter subsequently secreted. This matter, according to PAYEN, is assimilated through a funnel-

Fig. 537.

Case 1.

Case 2.

shaped opening in the granule, usually, though improperly, called a *hile* or *hilum*. This aperture is visible in many varieties, and sometimes grains are found to have two or three of them, especially when the

corpuscles are large; and even when imperceptible under the usual magnifying powers, they may be rendered visible by submitting the starch to careful desiccation, when the internal matter contracts, and thus causes an enlarged opening, which, sinking into the granule, exhibits the rings or discs usually observed in starch grains abutting against it, as seen in the annexed figure, exhibiting in Case 1 the starch granules with the hilum, and, in Case 2, the same after desiccation. These concentric rings or bands have led to much controversy as to the true organization of the starch corpuscle. It is generally supposed that it is made up of layers superimposed on one another, from the nucleus to the outer wall, and that the bands contracting towards the hilum result from the upper verge of such layers cropping out. Those maintaining this view hold that the matter in each differs neither in its nature nor composition, beyond being a little denser as the outer surface is approached. Those who maintain the opposite opinion assert that the corpuscles are true cells filled with the true amylaceous matter, and that the bands are simple plications of the walls of the cell.

When starch is moistened with alcohol of 0.85 specific gravity, and then slightly heated, the spirit evaporates readily, and leaves a slight particle of water

and gradually expand, developing at the same time a frill-like plicated margin, which slowly opens out; the plications on the globule may then be seen slowly unfolding, and may be traced in many cases into the rugæ of the frill. Ultimately the granules swell up to twenty or thirty times their original bulk, in which state they appear as flaccid sacs, though no extrusion of matter can be observed during the experiment.

The Editor finds REID argues, from the following endosmotic experiment, that the starch has an exterior covering or cellular membrane coating the inner substance, and that the latter is not organized in successive layers as if a number of sacs were arranged one within the other. He saturated starch granules with glycerin, and placed them while in this state in contact with water, when endosmotic changes followed, the less dense liquid being absorbed. After the absorption the grains were found to have burst in the direction of their axes, the rupture indicating a membrane that had been corrugated by release from unusual tension, whilst the covering of the remaining portion of the granule was visible in distinct longitudinal wrinkles from the hilum downwards. He submits that, were the corpuscle composed of superposed laminæ only, the addition of water in the manner described ought not to rupture it, or if this happened, the fracture would be in the direction of the laminar surfaces and not at right angles to them or their supposed order, as happened in his experiments. He further holds that the bands or lines observed in starch grains are mere plications of the outer membrane, because they entirely disappear on swelling the corpuscles with any liquid.

In direct opposition to this view may be placed the facts already stated of the combined effect of heat and solvents. Thus, if a little potato starch be heated on a metal plate to 360° or 390°, and then examined after treatment with a little water, the several layers will be found swollen, and by adding an aqueous solution of iodine they will be made to appear with considerable distinctness. The question, however, is not yet thoroughly answered, though the mass of evidence is in favor of the view that an outer cuticle surrounds the inclosed matter, from which, as well by the iodine reaction as by its less solubility, such coating differs in many of its properties.

In the annexed woodcut—Fig. 539—*a*, *a'*, *a''*, *c*, *d*, represent granules of starch heated to 320°, 392°, and 410°, as seen in alcohol; *f*, *g*, the same swelled in water after being heated to 320°, showing the hilum opening inwardly; *g*, granules of the same starch submitted to the last-mentioned temperature and afterwards plunged into alcohol, which, on evaporation, left a little water on the external part of the grain, and which dissolved a portion of the exterior matter; *h*, grains of starch heated between 392° and 420° and then put in water, when they swell to such a degree as to exhibit the different folds of their matter in the form of so many layers. These folds are more easily distinguished by adding a little of an aqueous solution of iodine to the liquid, in order to give them a violet tint.

Before passing to the consideration of the chemical properties of starch it may be well to give, in addition

Fig. 539.

on each grain, which, at the increased temperature, is acted upon more or less; and if the grains be placed in an excess of the liquid so as to remove the entire mass, nothing but a thin pellicle remains. Fig. 538 exhibits granules of potato starch thus treated; the granules, *a*, *b*, *c*, show the effect of the action of the drop of water; *d* shows the partial solution of the substance leaving the insoluble portion; and *e*, the swollen insoluble pellicle. According to BUSK, the best method for exhibiting the starch corpuscle under the microscope is, to saturate it with a concentrated solution of chloride of zinc containing a little free iodine. No change appears from these agents; but as soon as water is added, the grains assume a deep-blue color,

to the descriptive references in the preceding drawings, a few additional facts concerning those starches which form articles of commerce.

Fig. 539.

WHEAT STARCH.—The amylaceous corpuscles of wheat differ somewhat among themselves in appearance and size of grain, but generally they are composed of

Fig. 540.

large and small granules, with very few of an intermediate size. The smaller grains are chiefly round, rarely oval, and for the most part provided with the dark central spot or aperture designated the hilum; the large granules are rounded and flattened, so as to give them a lenticular appearance. In most of the grains neither the hilum nor the concentric rings can be distinguished with a magnifying power under four

hundred and sixty linear diameters. Viewed edgewise between glass plates, some of the grains seem misshapen, and present the appearance of a longitudinal furrow, occasioned by the partial folding or curling of the grain on itself; this has been erroneously described by PEREIRA as the hilum. In Fig. 540 are represented the structure and appearances of the starch granules of wheat flour, as also the characters of the cellulose, drawn with the camera lucida, and magnified four hundred and twenty diameters.

BARLEY STARCH—Fig. 541—is somewhat similar to

Fig. 541.

that of wheat, being composed of large and small grains; but the latter are three to four times less than the corresponding ones of wheat starch. This engraving represents the structure and characters of barley starch, together with the cellulose. It is drawn with the

Fig. 542.

camera lucida, and magnified one hundred and forty diameters. A considerable number of the large corpuscles has distinct rings and the furrow already referred to.

RYE STARCH.—This variety—Fig. 542—is similar to wheat starch in the form of the granules, but the smaller grains appear to be less than the analogous ones in wheat starch, and the others somewhat larger. In

addition to these differences, there is seen on the flattened surfaces of the larger grains of rye starch a three or four, or even five-rayed hilum or spot, which serves at once to distinguish the two varieties. This engraving represents the structure and characters of the starch granules of rye flour. It is drawn with the camera lucida, and magnified four hundred and twenty diameters.

OAT STARCH.—The corpuscles of this variety—Fig. 543—are much smaller, but more homogeneous, than those of wheat or barley; and instead of being circular, they have a polygonal outline, and are devoid of visible rings or hila. Many of the granules remain connected, presenting rounded or oval bodies, with a reticulated

Fig. 542.

surface, indicative of their structure. Another well-marked difference is, that the granules of oat starch do not show the usual crosses when viewed with polarized light that the other cereal starches exhibit under the

Fig. 544.

same circumstances. This engraving represents the structure and characters of the starch corpuscles of oat flour, as also of the cellulose. It is drawn with the camera lucida, and magnified four hundred and twenty diameters.

VOL. II.

MAIZE OR INDIAN CORN STARCH.—This—Fig. 544—resembles in a great measure oat starch in the polygonal outline of its granules, but the corpuscles are much larger, and do not aggregate to form compound bodies, as is the case with oat starch. Under the polariscope maize starch presents well-defined crosses, and, like all the other amylaceous organization of the cerealia, exhibits the central depression of the grains very well marked. This engraving represents the structure and characters of the starch granules of Indian corn flour, including the cellulose, drawn with the camera lucida, and magnified four hundred and twenty diameters.

RICE STARCH.—This variety—Fig. 545—representing the starch corpuscles of rice flour, drawn with the camera lucida, and magnified four hundred and twenty diameters—presents the appearance of very small polygonal grains, more angular, however, than that of the

Fig 545.

oat or maize; it has a well-marked central depression in the grain, the edges of which appear raised. They resemble the starch from the oat grain, by their aggregating together and forming in rounded masses. The preceding figures, representing the starches referred to, are taken from HASSALL'S *Adulteration of Food*.

CHEMICAL PROPERTIES OF STARCH.—Viewed chemically, starch may be regarded as a definite compound of water and the true principle of organic formation bearing this name, or *amylum*. If the substance, after extraction from the plant which yields it, be allowed to deposit from the water in which it is held in suspension and then dried by pressing between absorbent media, such as plaster of Paris, till no further loss is sustained, it will be found still to retain forty-five per cent. of its weight of moisture. On exposing this product to moist air at a temperature of 68°, the weight of water will ultimately be reduced to thirty-five per cent. At this degree of desiccation the starch appears of snow-white brilliancy, possessing remarkable cohesive properties, so much so as to allow its being readily pressed into plates possessing a considerable degree of tenacity, and capable of receiving an impression from hard bodies without, however, yielding any moisture to an envelope

6 D

of bibulous or other paper in which such plates may be inclosed. It is impossible to sift it whilst in this state, and when projected upon metal plates, heated to 300°, the particles agglutinate into compact masses. This property is turned to account in the manufacture of tapioca, sago, and the compounds sold as patent soluble starches, from ordinary fecula or wheat starch.

When the starch which has been desiccated in moist air for several days, is exposed to the circulation of a dry atmosphere, it parts with a further quantity of water, which reduces the per centage of that ingredient to eighteen, and in this state it possesses a very slight adhesive property, but not to such an extent as would prevent it from passing through the meshes of a fine sieve; neither does it swell up or agglutinate as before. Thus dried, it constitutes the ordinary commercial starch. Air-dried fecula of this nature loses a further quantity of moisture when kept in a vacuum at a temperature of 60°, so as to leave only fifteen per cent. combined; and if the heat be sustained at 260°

the moisture is reduced to a minimum, or eight and a half per cent. Starch so dried constitutes a monohydrate of amylin or of the true starch principle, from which mere desiccation cannot remove more water without altering or destroying the order of combination of the elements entering into its composition. It is only by combining the matter of starch with metallic bases, such as lead or baryta, that it can be obtained in a perfectly dehydrated state, in which it exhibits upon analysis the following composition, corresponding with the formula $C_{12}H_9O_9$:—

	At. Weight.	Centesimally.
12 Eqs. of Carbon = $12 \times 6 = 72$	72	47·059
9 „ Hydrogen = $9 \times 1 = 9$	9	5·883
9 „ Oxygen = $9 \times 8 = 72$	72	47·058
	153	100·000

By tabulating the results above referred to, the relation between the amylaceous matter and the combined water will be more easily comprehended :—

Condition of Starch.	Formula.	Atomic weight of Starch.	Per centage of HO in thoroughly dried Starch.	Per centage of monohydrate of Starch.
Anhydrous amylin,.....	$C_{12}H_9O_9$	153	0	0
Starch dried at 212° to 280° <i>in vacuo</i> ,.....	$C_{12}H_9O_9HO$	162	0	100

Starch dried in air saturated with moisture,.....	$C_{12}H_9O_9HO$, 10 aq.	252	35·71	64·39
Starch thoroughly drained by absorbents,.....	$C_{12}H_9O_9HO$, 15 aq.	297	45·45	54·55

When subjected to a heat ranging from 395° to 410°, starch is readily converted into dextrin, but some kinds are more easily acted upon in this way than others. If a certain amount of water be contained in the starch, the heat necessary for its transformation is not so great. Thus, when starch dried in a vacuum at 260° is subjected to a temperature of 320° in an oil bath, it does not suffer much change, and retains its property of insolubility in cold water; but when the temperature is raised to 395°, and sustained at this degree for half an hour, the starch becomes altered to an amber color, without, however, giving out much water, and the chief part is dissolved by cold water. It is different with fecula containing four equivalents of water, which, if suddenly brought to 320° to prevent the evaporation of the moisture, passes at this degree into dextrin, so that the effect is in all things nearly the same as if the substance were quickly heated in the air to 395° or 410°. According to JACQUELIN, the changes that follow an increase of temperature applied to starch merely air-dried are these :—From 212° to 284° the hilum is more and more developed, appearing in the end like a large rent or tear; at 320° the granules lose their ordinary form; at 338° the inclosed starchy matter becomes soft and slightly colored; at 356° it turns black, and is soluble; and at 372° to 395° the walls of the grains burst asunder.

Such are the changes which heat alone effects upon starch; they are somewhat different from those that are produced by other agents.

Potato starch or fecula suspended in twelve to fifteen times its weight of water suffers no change, not even when the temperature is raised to 131°, with the exception of a slight increase of the younger or more

tender grains; at 135°, however, the corpuscles perceptibly swell, and continue to do so as the heat advances; at 162° the increase of the granules becomes more evident, and the liquid assumes more or less consistency, which goes on increasing up to 212°, when it forms a paste of greater or less thickness. If the proportion of the fecula and water be as one to a hundred and the mixture be boiled, the white color of the corpuscles disappears and the whole presents a perfect solution, so much so as to traverse a compact filter; yet a finer filtering medium can separate the starch so as to make it appear that, instead of being dissolved in the liquid, the corpuscles were only largely distended and diaphanous. PAYEN, by immersing the bulb of a hyacinth in such a filtered solution, succeeded in separating the apparently dissolved starch; for there appeared, as the rootlets absorbed the water, particles of starch adhering to them, which were turned blue by iodine, whilst a section of the roots of the bulb gave no indication with this test of the presence of amylaceous matter. Hence it is evident that the fine capillaries of the plant, being too small to permit the passage of the particles of starch, caused their accumulation on the surface—a circumstance which, it may be supposed, would not occur if the starch were perfectly dissolved. Not only is the starch separable from its apparent solution by the means just mentioned, but it is precipitated by cold even when the quantity of water is more than double that mentioned in the last experiment. By submitting starch paste made with fifteen parts of water and one of starch at 212°, to cold sufficient to freeze it, and then allowing it to thaw, a contraction of the paste takes place, and it parts with a portion of its water. By repeating the operation, the

starch, which was apparently soluble in water whilst in the form of paste, becomes quite insoluble, and precipitates from the liquid in flakes. Advantage is taken of this property to obtain a felt-like substance suitable for certain kinds of cartridges, and for other purposes to which paper is inapplicable. The paste, after being cooled below zero, is then heated slightly above the freezing point and submitted to pressure, when most of the water is expelled and a dense felt-like matter remains, applicable for the above uses. Even when the quantity of water in which the starch is boiled is two or three hundred times greater than the weight of the starch, it is found that by repeatedly freezing and liquifying, the menstruum and the starch separate in flakes. From all these circumstances it appears doubtful whether starch is entirely soluble in hot water.

Solutions of the fixed alkalis have the effect of swelling the corpuscles of starch, and causing it to form a paste even without the aid of heat. Mixed with an alkaline solution containing from one and a half to two per cent. of alkali, the starch granules appear to swell, when viewed under the microscope, to the extent of seventy-five times their original bulk. By previously drying the starch *in vacuo* till it becomes a monohydrate, the absorbent qualities seem to be considerably increased, for when such fecula is treated with a liquid containing only one per cent. of alkali or less, the enlargement is so great as to rupture the cell walls of the grains, and cause the starchy substance or amylin to protrude and become diffused in the liquid.

When the quantity of alkaline water is not in too great abundance, it converts the starch into a semi-transparent paste, in the same manner as water. It would appear that a salt of the alkali is produced in this operation, in which the starch forms the radical, and from which the insoluble amylates of the alkaline earths or metallic bases may be obtained by simple double decomposition, upon the addition of a neutral soluble salt of those bases. The decompositions in these cases are so complete that, when an equivalent of the precipitant is employed, the filtrate from the precipitate does not, upon the addition of iodine, give the slightest indication of the presence of starch; the iodine will not give the usual reaction of starch with the precipitates till after their decomposition with a weak acid, such as acetic.

From the analysis of the amylates of lime, baryta, lead, and silver, the composition of the true matter of starch, as previously stated, has been deduced.

Sulphuric, hydrochloric, and nitric acids in a diluted state have also the power of swelling starch and converting it into a paste. When sulphuric acid is employed, the proportion of acid in the liquid should form at least three per cent. of strong acid. If, in addition to the effect of dilute acids, the temperature of the solution in which the starch is held be raised to 212°, several changes follow, the first of which is the production of dextrin, a substance isomeric in composition to the true amylaceous matter that is soluble in cold water, and in its properties analogous to gum; the next change appears to be the formation of glucose or grape sugar, a body which differs from starch merely by two equivalents of water, or rather of oxygen and

hydrogen; for these elements are assimilated so that they constitute an integral part of the new compound. Its formula is $C_{12}H_{12}O_{12}$, but as it crystallizes from the liquid it takes two equivalents of water of hydration, in which state it may be represented as $C_{12}H_{12}O_{12} \cdot 2HO$ or $C_{12}H_{14}O_{14}$. These changes take place to a large extent with starch paste made simply with water by the aid of heat, by mere exposure to the air. Thus one hundred parts of wheat starch made into a paste with twelve hundred of water, and the mixture exposed during thirty-eight days, was found by SAUSURE to yield—

Sugar,.....	47
Dextrin,.....	23
Starch granules,.....	8
Starch,.....	4
„ altered,.....	10
	92

The difference in this instance must be attributed to the change in the composition of the substance. This was shown by taking the same weight of starch, treating it as above, and allowing the same period of exposure; it was then analysed, and the results showed a loss of one fifth, thus :—

Sugar,.....	50
Dextrin,.....	10
Starch granules,.....	5
Starch,.....	4
„ altered,.....	9
Carbonaceous matter,.....	0.3
	78.3

A disengagement of carbonic acid accompanies this decomposition when it takes place in the air; if on the contrary, the reaction take place in close vessels, bubbles of hydrogen are evolved from the mixture. In these cases it is probable that the small proportion of gluten in the starch, generating diastase by decomposition, renders the change more active; for it is well known that diastase will convert starch into dextrin and sugar, to the extent of two thousand times its weight.

The starch granules mentioned in the preceding analysis are such as settle down from a solution of starch in water at 300° when the liquid is left to cool; these granules are dissolved in water at 160°, or better when the heat is so high as 212°, and the liquid affords the ordinary reaction with iodine. It appears from the experiments of JACQUELIN that they are permanent, and may be reproduced from their solution in boiling water by simple evaporation in their original form; they are insoluble in cold water, as may be proved by iodine, but when rubbed in a mortar and then diluted with water it is probable that some of the grains are fractured, for on testing the liquid it manifests the presence of starch. The best method for obtaining this permanent form of starch is to digest a mixture of one part of fecula and five of water in a PAPIN'S digester at 300° for two hours, and afterwards to allow the mixture to cool. Should the heat rise to 320° the fecula would be converted chiefly into dextrin, with a little sugar giving a violet color with iodine; on the other hand, if the heat approaches 355° the sugar predominates and very little dextrin is found, so that iodine has no effect upon it.

It has been already mentioned that dilute nitric acid converts starch, equally with dilute sulphuric acid, into dextrin and sugar, after swelling the granules and transforming them into a pasty mass, when the water is not in excess. The result of the action is very different when strong nitric acid is employed. BRACONNOT found that fuming nitric acid, specific gravity 1.5, when poured upon starch or fecula, dissolves it, and on the addition of a large quantity of water a substance was precipitated, which, when freed from excess of acid by washing and dried, proved to be highly inflammable and soluble in ether; this is the xyloidin or nitramidin of PELOUZE, who found it to be composed of one equivalent of starch with one of nitric acid. With the same acid, and the application of heat, starch is converted into a number of indefinite substances, which ultimately resolve themselves into oxalic acid. This operation, with slight modifications, is followed in the manufacture of the latter article as will be seen by referring to page 637 of this volume.

Hydrochloric acid causes the alterations of starch already mentioned into dextrin and glucose, first forming a jelly, or dissolving the substance according as the quantity of water present is greater or less. Its action is far less energetic, however, than chlorine. The latter element has invariably a decomposing action upon starch, which results in the production of water and carbonic acid. These changes take place even when a solution of hypochlorite of lime—bleaching powder—is put in contact with starch in the cold, but the decomposition is gradual. With an excess of the reagent the transformation is more rapid. Oxalic, tartaric, and other acids have the power of swelling the starch grains, and ultimately converting them into dextrin or glucose. Acetic acid is devoid of this power, and therefore the fecula remains quite unaffected by it. The same inertness is exhibited by ammonia towards this body, and hence the following method by PAYEN, for the valuation of vinegar and ammoniacal salts:—He adds about a five-hundredth part of the sample of ammoniacal salt to be tested, of starch to the solution in which the former is contained, and then drops in a standard liquid of caustic-soda till the menstruum indicates the swelling of the granules and the formation of a paste. Previous to this result, the soda displaces the ammonia by combining with its acid; but after the whole of the ammoniacal salt is decomposed, the soda that is added in excess reacts upon the starch, and converts it into a paste. Vinegars unadulterated with mineral acids have no action upon starch, so that when a mixture of the two is boiled, the peculiar reaction of starch and iodine is exhibited unchanged; but if the acid be adulterated with sulphuric or any other mineral acid, the change of the fecula to dextrin and glucose will be proportionate to their quantity, and this alteration will be exhibited by the iodine reaction. The tests, however, considered analytically, are of little value.

The most remarkable property of starch is the combination it forms with iodine, and which is characterized by the well known blue color of the compound.

This reaction, besides being the most sensitive test yet discovered for the mutual detection of starch and

iodine, has many other important applications with reference to the changes which the fecula undergoes under the influence of other agents. When a weak solution of iodine is added to starch the blue coloration takes place, but it is so superficial that the granules appear transparent when observed under the microscope. If the quantity of iodine added be greater, the coloration becomes more intense, and to such a degree as to cause the corpuscles to appear black; this blackness and opacity take place when only one two-thousandth of a millimetre in thickness. As the combination proceeds through the entire mass of the granule, the whole appears of a beautiful blue. Between this characteristic blue shade, every gradation of tint is observed till a reddish or orange color manifests itself, according as the starch is disaggregated and changed into dextrin and sugar under the influence of a hot solution acidified by sulphuric acid, or any other body capable of producing the like effect. Thus, a solution of starch in boiling water, when iodine is added immediately, forms a fine blue precipitate; and then by pouring in some sulphuric acid, and maintaining the heat, it gradually changes to various shades of violet, afterwards to wine-red, then to a crimson-red, and finally to an orange-hue. Some of these shades are produced when iodine is added to starch in its progressive stages of development. Young or imperfectly formed starch granules, in which the matter is not properly aggregated, produce with iodine a reddish-fawn color; and as the particles become more united and compact the tint changes through the several stages of violet, in which the blue predominates, till ultimately, as the granules are fully formed, the tint resembles that of indigo.

There are many evidences that the result of this action is a true combination of the starch and iodine. If the compound be kept at 60° *in vacuo*, it retains nearly as much water as the starch itself under the same treatment. When the compound is partially desiccated in the vacuum, and the heat is afterwards raised to about 425° to 430°, a portion of the iodine is expelled, but on cooling the substance again by contact with the air, the shade of color still remains very deep. On adding a little water to the compound, and repeating the experiment under the same circumstances, a further amount of the iodine is displaced though the color is not eliminated. Treated with water at this stage of the experiment, only about two per cent. of the starch is dissolved, and this soluble portion even strikes a violet color upon the addition of a little iodine. Upon examination, many of the granules of the insoluble portion are so highly tinted as to appear black, and these resist the action both of the alkalies and concentrated sulphuric acid in the cold, thus showing that a very strong combination has taken place.

Starch dried at 212° to 266° in a vacuum, and suspended in absolute alcohol, does not unite with iodine dissolved in the same menstruum; but if a little water be added, a violet coloration, which deepens in shade by standing, is immediately produced. From this behavior it might be anticipated that alcohol would abstract iodine from the amylaceous compound. This is to a great extent the fact, for on agitating the blue

compound with about twenty times its weight of absolute alcohol, and decanting the liquid after the matter subsides, a portion of the previously combined iodine will be removed; and by a repetition of the process, fresh quantities will be taken up, though less each time, till as much as four-fifths of the combined iodine is separated. When the solvent is employed at the boiling temperature, the decoloration is much more rapid; and if a portion of the substance be viewed under the microscope whilst the reaction is taking place, it will be noticed that the least aggregated of the corpuscles, or in other words, the younger ones yield their iodine first, and turn to a violet and red color. The granules of starch do not lose their distinctive character by combining with iodine, for if the blue iodide, dried thoroughly at 212° in a vacuum, be examined under the microscope in the presence of absolute alcohol, the corpuscles will, as they become decolorated, appear intact. If, however, a few drops of water be added to the alcohol employed whilst the substance is under examination, or after it has been dried, several of the grains appear as if burst; the inclosed matter being disseminated in the liquid and colored reddish-violet, the coats of more aggregated matter acquiring by the hydration a shade approaching to a blue.

The blue iodide of starch is decomposed by several agents. Exposed to the light of the sun, it gradually loses its blue color in the presence of water; the effect is more rapid when the menstruum is raised to a temperature of between 86° and 105° . In either case the changes result from the decomposition of water, the hydrogen of which enters into combination with the iodine to produce hydriodic acid, the oxygen forming iodic acid with another portion, so that the mixture becomes colorless. When starch is freshly treated with iodine, the alkalis readily decolorize the compound, owing to an iodide and iodate of the alkali being produced, leaving the starch almost intact in the solution. It is a very curious characteristic of the iodide of starch that, by a change of temperature alone, the blue color may be made to disappear and return several times in succession. If an excess of iodine be poured into the solution of starch the blue iodide will be retained for some time, even at 212° ; but when the excess of this element is volatilized by the heat, the compound fades, and even a heat not exceeding 160° will be found capable of reducing the color of the mass completely. On allowing the vessel to cool, however, the blue tint, strangely enough, reappears, and this alternation of color can be repeated by heating the solution, and allowing it to cool again. By degrees, the tint weakens each time the solution is cooled, owing doubtless to the loss of iodine sustained either by expulsion in the form of vapor, or by conversion into hydriodic acid. The blue tint is retained with much greater tenacity when the amount of starch present is greatly in excess of the iodine.

Iodide of starch precipitates very readily from its solutions however dilute; but the coagulation of the matter takes place much more readily in presence of the neutral salts of the alkalis and alkaline earths, and of dilute acids, and even by a reduction of temperature. In all of these conditions the separation is to

be attributed to a very marked contraction which the iodine by its union causes in the corpuscles of starch.

It has been stated that water at a high temperature, acid, and alkaline solution have the power of swelling the granules of starch to such an extent as to render them apparently soluble when the volume of water is very large, or to produce a semitransparent jelly, when its quantity does not exceed a certain limit. In the latter case the increase in the granules is greater than the volume of the liquid in which they are held; and, consequently, instead of moving freely as in a solution, the swollen grains are compressed and ramify into one another till the whole becomes as it were soldered—at which stage the mass appears a jelly. When iodine is added to such a mass a reverse change succeeds; and the contraction of the grains enables the compound to precipitate readily, so that, in a short time, the blue iodide will be retained on a filter from the liquid portion. In a very dilute solution of starch the precipitation of the iodide is not so rapid as in menstrua of greater density. Congelation, in such cases, causes the blue compound to form in flocculi in the liquid; and in time they settle to the bottom, leaving the rest of the liquid colorless. Cold has an analogous effect upon fecula which has been distributed in a large quantity of water, and subjected to a temperature of 212° ; for, by repeated freezings and solutions of the frozen mass, by successive applications of cold and heat, the starch grains which before had seemed as if dissolved, owing to their great extension, now appear in flocks in the liquid, and can be separated from the latter by simple filtration. In both cases a considerable amount of contraction takes place, to which the separation of the starch, in one instance, and of its iodide in the other, is to be attributed. One equivalent of iodine can fully saturate seven of starch in producing the blue iodide; the ratio of combination between them is therefore as seven to ninety-two by weight, and by volume as one to twelve.

Tannic acid seems to form combinations with solutions of starch, giving a greyish-white flaky precipitate, which becomes transparent in the heat, but reappears in the usual form as the liquid cools. This acid decolors the blue iodide of starch, and when present in sufficient quantity it prevents the entire decomposition of fecula by means of diastase. The reaction contributes in part to the formation of artificial leather on CLAUSEN'S principle, as already detailed in this work.

Amount of Starch contained in different substances.

—The quantity of starch in different grains and bulbous roots yielding this substance, varies considerably, both in the per centage, amount, and gross total yield per acre; and these two circumstances must be taken into consideration by the manufacturer in selecting one in preference to another of the many sources whence the starch is extracted. Thus while the potato affords centesimally only from fifteen to sixteen parts of starch, wheat affords as much as sixty per cent.; still the total amount per acre is in favor of the potato in the ratio of 2400 to 996; the produce being estimated at six tons in the first instance, and sixteen hundred-weight in the latter.

Different varieties of the same species of grain likewise exhibit a marked difference in the amount of starch, as appears from the following table :—

AMOUNT OF STARCH IN DIFFERENT KINDS OF WHEAT DRIED AT 212°.

	Per cent.
Talavera wheat from Hohenheim,.....	56.25
Whittington " ".....	52.45
Sandomierz " ".....	53.37
Wheat from Giessen,.....	54.63
Do. from Vienna, No. 1,.....	65.68
Do. " No. 2,.....	67.17
Do. " No. 3,.....	67.45

A difference as remarkable is exhibited in various kinds of potatoes. Thus JOHNSTON found in—

	Per cent.
Red potato from Lanarkshire,.....	14.08
Small Americans,.....	17.80
Orkney potatoes,.....	17.42
Buffs from Forfarshire,.....	20.71
Kidneys,.....	14.93
Cups from Argyleshire,.....	15.41

Mr. HEMING gives the following numbers as the per centage of starch from different varieties of potatoes grown on the same soil in Renfrewshire, namely :—

	Per cent.
Irish blacks,.....	16.5
Connaught cups,.....	21.0
White dons,.....	13.0
Red dons,.....	10.75

This variation is the more remarkable when considered with reference to the quantity produced per acre :—

	Quantity per acre.	Amount of starch.
	Tons.	Tons.
Cups,.....	13.25	2.9
White dons,.....	18.50	2.4
Red dons,.....	14.25	1.5

It may be presumed that much of the discrepancy in the quantity of starch indicated by the foregoing analyses is to be attributed to the age of the tubers; but though the amount of fecula certainly varies at different periods in the growth of the plant, still the experiments that have been made to elucidate this question conclusively demonstrate that even at maturity the quantity of the starch is unequal. The per centage of starch which any given variety yields, depends very much likewise upon the nature of the soil and the weather which has prevailed during harvest, the yield being much less in dry than in wet seasons. Potatoes that have been allowed to remain a considerable time in the ground, or being improperly stored, have become heated and budded, will not be found to contain as much fecula as others of the same kind which have been timely collected and carefully stored; for the sprouting effects the decomposition of a considerable portion of the starch. This is well known in potato-starch factories; for whilst, in the months of October, November, and December, as much as seventeen per cent. is obtained, in January, February, and March, the amount diminishes to fifteen and even twelve per cent.

There is no difficulty in inferring from these facts the advantage gained by extracting the fecula from potatoes during the three months after they have arrived at maturity, rather than at a more advanced

season. Analysis of the potato shows that it is composed centesimally of—

Water,.....	74.00
Fecula,.....	20.00
Epidermis, cellular tissue, pectose, pectine, pectates of lime, soda, and of potassa,...	1.65
Albumen and analogous nitrogenous matters,.....	1.50
Asparamide,.....	0.12
Fatty matters,.....	0.10
Sugar, resin, essential oil—solanine,.....	1.07

Blue potatoes,.....	23.20	22.80
White potatoes,.....	16.14	17.98
" ".....	16.48	16.09

The potato has long been resorted to for the preparation of the cheaper kinds of starch; but, in addition to this source and wheat, from which the finer kinds are made, other matters—such as rice, maize, and barley—are employed in the manufacture. Wheat and other cerealia having been first employed, claim precedence in describing the process on the large scale, notwithstanding that at present these materials are not so generally resorted to as in former times, unless when to some extent damaged, and, therefore, not so well adapted for human food.

MANUFACTURE OF STARCH.—In the manufacture of starch from the cerealia two methods are followed, which may be distinguished as the fermentative or old process, and the chemico-mechanical, or modern and improved method. That the improvements introduced of late years in the manner of making starch possess a decided advantage over the old system, cannot for an instant be doubted, and yet in many factories the old process by fermentation is still followed; a method both noxious and wasteful. By this process, the wheat is first steeped till softened, and then coarsely ground in a malt mill, or crushed between rollers; the crushed mass is made into a thickish creamlike consistence with water, generally the acid water from a previous operation, and allowed to remain in vats or tuns for a period varying with the temperature of the weather from ten to thirty days. The effect of this prolonged steeping is to disintegrate the starch from the glutinous envelope in which it is contained in the grain; an effect produced by the gluten being partly

decomposed by fermentation, partly dissolved by the acids formed in the course of the operation, and partly by its property of becoming partially soluble on entering upon the putrefactive change. At first any sugar in the grain, or dextrin produced in the first stages of the process, is dissolved in the water, accompanied by a slight alteration of a portion of the gluten, whereby diastase is formed in more or less quantities; this sugar and dextrin are converted into alcohol and carbonic acid, and by prolonging the operation the spirit is changed to acetic acid. To equalize the action it is necessary to agitate the mass once or twice a day, and likewise to beat into it those portions which the escape of carbonic acid during fermentation may bring to the surface. After a few days the glutinous portion of the grain begins to undergo the putrefactive change more or less rapidly, and this proceeds till it is considered sufficiently advanced to allow the starch corpuscles to be separated in a state of comparative purity. By such changes, ammonia, sulphide of hydrogen, and other disagreeable products are formed, which renders the operation noxious, and often a most offensive nuisance. After the fermentation is supposed to be completed, any excess of water that may happen to be in the fermenting tun is drawn off, and the magma or thin pulpy mass is filled into bags of stout canvas, or other material, the mouths of which are afterwards well secured; they are then placed in water, and trodden upon till the water is quite loaded with starch, when it is drawn off, and its place supplied by fresh liquid; the treading is then repeated till the solution again becomes quite creamy with starch, and this, in like manner, is let off as before. Three or four such washings exhaust the bags of the starch, leaving only the husk of the grain and the altered albuminous matter, which is almost useless. The starchy liquids are made to pass through hair-cloth or wire sieves in their course to the settlers, to deprive them of any portion of husk or fragments of glutinous matter, after which they are allowed to repose in the settlers for several days; the starch sinks and forms a cake of solid matter on the bottom, whilst the more glutinous portion afterwards constitutes a deposit of a brownish color above it. Frequently, in order to delay the deposition of the glutinous matter, very light and finely-divided fibrous matters are introduced, and agitated with the liquor; the glutinous particles by attaching themselves to the fibres of the extraneous substance employed, are retained in the water a much longer time than the starch, so that the under layer of the deposit is almost in a state of purity whilst the gluten and fibre settle down upon it. After drawing off the clear water by a siphon, the impurity on the top of the deposit is separated and set aside to be washed with the next batch; the underlying portion is stirred up with fresh water, and purified by settling and decantation; this operation being repeated twice, thrice, or oftener if necessary. When the starch is sufficiently white, it is put to drain into small boxes, the sides of which are lined with flannel; or it is dug out in lumps from the bottom of the depositing vessel, and placed upon blocks of plaster of Paris, which absorb the

moisture, and thereby cause the starch to harden. The deposit in the drainer boxes is similarly desiccated before it is sent to the drying-room.

Bran, and other refuse matters of the wheat, *et cetera*, are generally mixed with the grain in these operations, and increase the amount of the product.

When the gluten is of such a nature as to agglutinate easily, it can be separated by careful manipulation, but not so, without additional labor, when it disintegrates and passes off with the starch into the water. The extraction of starch from the cereals and leguminous seeds is now much simplified by the aid of chemical substances, and consequently the older system is but rarely practised. The length of time which it required, the labor involved in the process, the loss of starch occasioned by its transformation into dextrin and sugar, and finally, the disagreeable and unhealthy effluvia which were evolved, all concurred to render the old process far inferior in every respect to the modern one. In fact the new process introduced by MARTIN offers so many advantages that one might expect it to be universally adopted by the manufacturers of starch from wheat or flour; yet the old system is still practised in a number of factories, the conductors of which allege that the product obtained from the fermentative process has a better color than that prepared by the chemico-mechanical system.

In MARTIN'S process flour is employed in preference to wheat grain or the same coarsely crushed. It is made into a stiff dough with water, and allowed to remain in that state till every part becomes thoroughly saturated with moisture. A mechanical kneader may be employed with advantage to effect this part of the work. The time allowed for the water to permeate the mass varies from half an hour in summer to two hours in the winter season. The inventor employs a trough covered with a wire-gauze sieve, No. 120, to which a pipe and tap supplies a constant stream of water for washing the dough, the water being thrown upon the mass from a rose of forty minute apertures. The workman takes a mass of dough, averaging ten pounds, and placing it under the small jets of water, kneads it on the sieve till the water ceases to flow off milky, using at first only a gentle pressure, which is increased towards the end of the operation. By this careful working, the gluten, which at first is finely divided in the dough, is made to agglutinate into a pasty elastic mass, which becomes more consistent in proportion as the starch is removed, till ultimately nearly pure gluten remains. Another mass of the dough is then operated upon in the same manner, the gluten being each time separated and removed. In this way almost the whole of the gluten is disengaged from the starch. To remove the particles of gluten which accidentally pass through the sieve, the amylaceous washings are allowed to remain for twenty-four hours at a temperature of 70° or thereabout, together with the scum which formed upon the produce of a preceding washing, with the view of inducing fermentation, and thus altering the small portions of gluten still retained. The purification of the product is effected in the ordinary way by successive washings and decantations, taking the precaution, however, to draw off the liquor when

the dense portion has subsided, and before it becomes contaminated with the lighter particles held in suspension by the glutinous matter. On allowing these washings to settle for three or four days the suspended starch falls, and is recovered after the liquor is drawn off, drained in flannel-coated boxes, and finished on plaster and the drying stove. It constitutes about ten per cent. of the starch, and, although unfit for fine white goods, it forms a very good paste for colored stuffs, dressing, and the like.

MARTIN'S process is being daily more extended, especially in Germany, with decided advantage over the old system, not only in respect to the gluten which is extracted in the fresh state, and which constitutes a fourth of the weight of the flour, but likewise as regards the starch itself; for from average wheat flour as much as fifty per cent. is obtained, whereas on the old method not more than forty per cent. could be recovered. The cause of this loss is to be found in the change which the glutinous fermentation produces on the starch, and by which it is converted first into dextrin and then through the successive stages into glucose, alcohol, and acetic acid. These changes take place more rapidly in hot weather. By the new process, the gluten separated from the starch forms the basis of another profitable business, namely, the preparation of articles of food, such as macaroni, vermicelli, semolá, and such like; or it may be compounded with other articles, such as flour or potato meal, and made into a wholesome and substantial bread. In summer the gluten separated from the starch retains its freshness fully twenty-four hours; but after this it begins to lose its tenacity, enters into partial solution, and then decomposes; in the winter season it may be retained for two days without injury.

At first it was proposed to utilize the gluten by mixing it with potatoes or inferior flour, and making the compound into bread; but subsequently it was found preferable to mix it with boiled potatoes, in consequence of the insipidity of the compounds with potato starch. The manufacture of vermicelli and macaroni did not at first succeed, in consequence of the proneness of the gluten to decomposition; but this obstacle has now been overcome, and the gluten is made into a highly nutritious and palatable food, for which purpose the patent process of VERON of Vienna is the most applicable. In this method the gluten, after the separation of the starch, is mixed with twice its weight of best flour, and placed in a machine consisting of two concentric cylinders, the inner one of which is furnished with projecting pins, and is made to revolve much more quickly than the outer; the glutinous substance is thereby divided into a mass of elongated grains, which are placed upon trays and dried in the hot-air compartment along with the starch for the space of one and a half to two hours. The whole is then sifted to separate the finer from the coarser particles, and the latter is ground in a mill and resifted. The very rich nitrogenous compound thus prepared offers advantages over macaroni and semolá, owing to the readiness with which it may be prepared into food.

Such are the main features of the process followed in manufacturing starch from wheat, grain, or flour;

the details of the manufacture will be more fully given when treating of potato starch or fecula. At present it may be remarked, however, that the different qualities of starch to be met with in the market are simply the successive deposits, or the portions which subside in succession in the tuns or vats within a given period. It may be likewise stated that, with the view of giving a purer whiteness to the product, it is submitted, either in vats or in close chambers, to the action of chlorine or of sulphurous acid, either dissolved in water or as gases. By a slight elevation of the temperature in the primary stages of the hot-air desiccation, the starch undergoes a change which causes it to dissolve in water at a lower heat than it otherwise would; the product so heated bears the name of *soluble* starch.

STARCH FROM POTATOES.—For a long time the manufacture of starch or fecula from potatoes has been rapidly extending in France, and has now assumed so much importance that it ranks, in money value, next to beet-root sugar. In England the practice is not so general, and its development has been much checked by the potato disease. It has been already shown that this esculent yields a large quantity of starch, and the product so obtained possesses all the qualities adapted for ordinary application in calico printing, *et cetera*; it is also extensively mixed with farina, for increasing its whiteness; it is employed in the confection of vermicelli, semolá, tapioca, polenta, and a number of other alimentary substances, distinguished by various designations; also in the formation of dextrin or artificial gum, grape sugar, sirups, molasses, wine, beer, alcohol, vinegar, and several other uses.

In large potato-starch factories it is necessary to have considerable storage room for retaining the tubers during the most part of the year; and care must be taken to obviate, as far as possible, the conditions under which the starch in the potato is liable to undergo alteration. Thus all affected or diseased potatoes should be carefully removed from those which are sound, and the latter ought to be kept in a dry atmosphere, and at a temperature as low as possible. Dry cellars or pits formed in the ordinary way, if dry at the base, and securely covered with straw and earth, serve for some time; but a well-ventilated barn or shed with grated floorings, one over another, whereon the potatoes may be laid to the depth of two feet, or thereabouts, will answer the end much better. In any case it is necessary that, during the spring and first of the summer months, the potatoes be turned frequently, so that any shoots which may be forming be broken, and the progress of decomposition in the substance of the bulbs be thereby intercepted.

Few operations are simpler than the extraction of fecula from potatoes; nothing further is necessary than the rupture of its cellular matter either by rasping or grating, so as to liberate the starch granules, and the washing of this pulp upon a metallic plate or stage by a stream of water, such washings being afterwards passed through a fine sieve. The solid matter of the potato is thus left on the plate, whilst the starch is carried off in the water, and separated from any grosser impurities by the straining or sifting.

Finally, the fecula is purified by washing and decantation, *et cetera*. Simple as this process may appear, it is divided into several distinct operations, which will be described in the order in which they are carried on in the French and other manufactories of fecula.

STEEPING THE POTATOES.—This operation, which is preliminary to the washing, and has in view the softening of the clay and other adhering gross matter, that they may be more easily removed, is performed in a large trough or vat, filled with water, in which the potatoes are allowed to steep during six to twelve hours, according to the quantity of the impurities.

THE WASHING.—The next operation is the washing

Fig. 546

which is effected by mechanical means and the aid of steam. Fig. 546, represents an elevated view of the machine employed, which consists of a hollow cylinder, *b b*, constructed of laths of wood or iron,

laid longitudinally from one end to the other, the distance between each being such as to permit of the escape of the dirt, stones, *et cetera*, whilst the tubers are retained. The cylinder is charged from a hopper, *a*, at one end, and being slightly inclined, the washed potatoes are discharged at the opposite end, down the inclined plane, *d d*. About a third of the cylinder is immersed in the water of the trough, *c c*, wherein it revolves, and from the sides of which spring the boards, *g g*, slanting to the upper part of the cylinder, and intended to prevent the splashing of the water during the movement of the machine. This cylinder is worked by a band passing over the wheel, *f*, at the end of the axis, and a drum-head of another shaft in connection with the main shaft of the engine. The inclined plane upon which the potatoes fall when thrown out conducts them to the rasping machine.

RASPING OR GRATING.—The object of the rasping is to reduce the tubers to a pulp, by which the cells containing the fecula are ruptured; and the finer this rasping is effected, the more freedom will the starch have in escaping. In some instances, this operation is performed by means of a hand-machine; but generally, the larger factories adopt a machine by which the rasping and the washing of the pulp are effected consecutively. The circular drum bearing the rasp is turned by a winch handle, and while revolving meets the tubers in the hopper, reducing them to a pulp which falls by the aid of inclined boards into a vessel moving on wheels, and on which it is carried to the washing stage. A small stream of water is conducted on the upper surface of the rasp, with the view of keeping it clean from accumulation of pulp. The rasp itself

Fig. 547.

is made of plate iron, punched from the reverse side with an angular, semicircular, or round tool on a yielding support, which allows the angular fractures of the iron on the under side to remain unflattened. With a machine of this kind, from two and a half to three tons of potatoes can be turned into pulp by three men in twelve hours. The other kind of machine is

shown in Fig. 547, in connection with a portion of the washing apparatus. It consists of a cylinder about twenty inches diameter, and the same in length, mounted upon an axis. The cylinder is armed with steel-saw plates, placed at the distance of little more than three-fourths of an inch apart; the teeth of these saws, which are very small and regular, and placed

parallel to the cylinder, being held fast by iron clasps, project about four-fifths of an inch from the periphery of the drum, and the whole is turned with a speed of six to nine hundred revolutions per minute. Such a machine, making on an average eight hundred revolutions per minute, reduces to a pulp from sixteen to eighteen hectolitres of potatoes per hour, or forty-two and a half to forty-eight bushels.

In the preceding figure, the rasping drum is shown at *bb*; the inclined plane conveying the potatoes from the washing machine is indicated by *a a*, and the hopper into which the pulp falls by *c*, whence it is dropped into the washing machine by the trap-door *d*. The washing apparatus for exhausting the pulp, is that introduced by M. SAINT ETIENNE; it consists of a cylinder of wire gauze, *e*, fastened upon wooden or iron rings for support, and divided into two compartments, *j, l*, each provided with a wirecloth bottom, the lower finer than the upper one. The whole is inclosed in a sheet-iron or wooden covering, which prevents the escape of starchy waters from it when working. In the middle of the cylinder is a shaft, *g*, carrying arms furnished with brushes, *i, i*, which sweep the bottom disc of each compartment, and force out the fecula into a trough as the shaft is turned by the gearing of another one, *p*, acting upon a wheel appended to it at its base. By the very rapid

revolution of the brushes and agitators in the drum, aided by the stream of water projected from the rosed-pipe, *f*, the pulp is speedily washed, the fecula passing out at the sides and middle disc, *g g*, whilst the coarser pulp is thrown out by lateral openings, and is removed from the outer case by a door into the canal, *n*. The finer portions of the pulp, which pass through the upper part of the machine, are separated in the lower one; the granules of fecula falling through the fine meshes of the wire swept by the brushes into a trough, *m*, leading to the vats, *o, o, o*, where the starch is permitted to deposit, whilst the fibrous matter is ejected by an aperture at the side, and removed through a door in the case to the canal, *n*. In this form of machine there are several imperfections, which are obviated by a modification introduced by LAINÉ. The principal defects are, that the working is not continuous, the machine having to be stopped at intervals to remove the exhausted residue; that only comparatively small portions can be operated upon at once; and lastly, that the residue is not thoroughly divested of its fecula.

In the machine, improved by LAINÉ, and further perfected by DAILLY, the wire sieves are retained, but the washing space is considerably extended and prolonged, though the quantity of pulp exhausted in a given time is increased. This is done by

Fig. 548.

means of an inclined sieve, represented in plan and section—Fig. 548; a long inclined plane is constructed of planks, and this plane is converted into a kind of trough, by side planks, *a a*, secured in their places by cross planks, *i i*, and bolts, which fasten the latter to the base, *e e e*, of the plane. At each end are pulleys, *b b*, the crowns of which are notched in eight places, and into which the bars, *b' b'*, connecting the endless VAUCANSON chain, *c c c*, are caught and carried forward as the pulleys turn. Motion is given to these by connecting the axle of the lower one with the shaft of a steam-engine, water-wheel, or other motive power. Each of the eight divisions of the base of the inclined shallow sluice formed by the cross bars *i i i*, is covered with

a wire gauze, *d d*, increasing in fineness from the lower to the top one; and upon this finely-perforated surface the pulp to be washed is conveyed by the bars, *b' b'*, connecting both links of the chain as it travels from the lower to the upper end, in the slides at the sides and overhead, as seen at *f f f* in the figure. The chain and grooved slides on which it moves on its return overhead are supported by upright pieces of wood, bearing horizontal pieces, *g g*, on which the part *f f f* rests. From the rasping cylinder, or *cylinder devorateur*, as it is called, the pulp is conducted into the trough, *m*; and being diluted with the water employed to keep the cylinder clean, it overflows the inclined board, *n*, and so comes within reach of the cross-bars of the VAUCANSON'S chain as it travels over the lower

pulley, whence it is conveyed over the several compartments of the wire gauze in the inclined plane; but whilst in the act of passing upwards it meets with a stream of water projected from a pipe, *q*, along the upper three divisions of the plane, and which flowing downwards over the several frames, completely exhausts the pulp of all its fecula, leaving nothing but fibrous matter, epidermis, *et cetera*, when it reaches the top and is thrown out into the trough, *l*. From the three upper compartments the water projected upon the mass is conveyed to the lower ones in succession by a series of pipes, not shown in the drawing, connecting the several levels; thus from the lowest part of the highest square, a pipe issuing at the side conveys the liquor to the highest part of the third square; another from the lowest part of the second delivers the starchy liquid of this upon the fourth square, to meet the

ascending pulp; the third sends its water to the fifth, and so on to the lowest and first division, whence it issues into the canal, *r*, leading to the settlers. Two sieves and two travelling chains are generally worked upon the plane, provisions for which are shown in the drawing, the one movement working both. To avoid the inconvenience of the great length to which these planes extend on LAINÉ's plan, and also in DAILLY's, M. SAINT ETIENNE places the sieves one above another, and carries the endless chain over each, as shown in the drawing, by means of pulleys at the ends, the pulp being secured by a flange passing over the pulley and chain in each case. The pulp is delivered at once from the grater or *devorateur* to the chain carriage, and carried upwards till it is discharged at the top into the sluice exhausted of its starch. The disposition referred to is shown in Fig. 549, in which the principal

parts are similar to those last described. The water entering upon the top of the apparatus, flows from the highest of the compartments of each of the levels to the lowest, and thence upon the highest of that immediately beneath, and so on till it travels over the whole space to the base, where, loaded with the fecula, it collects in a receptacle, whence it flows by a pipe into a circular drum, *d d*, of very fine iron wire, revolving upon a central axis moved by mechanical power. Any pulp still retained is here separated and ejected into a receptacle, *e*, at the lower end, whilst the starch flows with the water through the gauze into the vat, *f*, and thence, by a *dénaiide* mounted upon the end of the axis of the cylinder, and revolving upon it, it is lifted into a sluice leading to the settlers, which are disposed as represented in Fig. 547.

By such a machine as the preceding, it is stated that the pulp from one hundred and sixty hectolitres—four hundred and forty bushels—of potatoes is exhausted in twelve working hours.

Besides the foregoing, several other inventors have constructed machines in which the advantages of uninterrupted working, combined with complete exhaustion

of the pulp within the smallest space, have been the points aimed at, and such advantages are claimed by HUCK, VERNIER, and STOLZ for their respective machines. All, with the exception of SAINT ETIENNE, have recurred to the cylindrical wire-gauze sifter, as being the one which affords the largest extent of surface in the smallest space. HUCK's machine consists of two wire-gauze cylinders, connected by a brass drum; in the cylinders are inclosed brushes and rousers, as usual, and also two drums, one for supplying pulp and water to the upper, and another in the lower for supplying water only. Both the wire-gauze cylinders and the drums move independently of one another and in opposite directions, the brushes and rousers taking the same course as the inner drums. The continued agitation in passing through both the cylinders, together with the action of the rousers, deprives the pulp of the most part of the fecula. The starchy liquid is collected in a cistern beneath, and flows into a third circular sieve in which only brushes revolve, but the wire of which is much finer, so that the last portions of pulp are separated. VERNIER employs a combination of three cylindrical sieves moving on the same axle; the

pulp arriving at the upper part of the first or smaller cylinder falls into it, and subsequently by the rotation of the entire system, as well as by the inclination at which the cylinders are fixed, it traverses each successively, being always exposed to a stream of water, till the exhausted matter finally issues partially drained from the middle one. The drainings from the sieves collect in a tank below the cylinders, and are thence conducted through another fine cylindrical sieve for depuration before they are run off to the settlers. STOLZ's machine is on the same principle as the preceding, and is said to be very effective, working off not less than four hundred and forty bushels of potatoes in a space of not more than twelve or thirteen feet. Whatever be the form of sieves employed, it is evident that the efficiency of the process depends in a great measure upon the quality of the rasping machine, and the fineness to which it reduces the tubers. On an average, only sixteen to seventeen per cent. of starch is obtained from potatoes really containing from eighteen to twenty or twenty-one per cent.; and therefore from two to four per cent. is left in the residue in consequence of the inefficacy of the *devorateur* to rupture all the cells containing the starch corpuscles. VÖLKER to obviate this, proposed to disintegrate the cells of the potato more completely than is done by the rasping machine, by submitting the pulp to a fermentative process, at a temperature between 68° and 86° in presence of sufficient water, by which the cells are in a short time destroyed, and the whole of the fecula is set free to be removed by a course of sieve washing. Though good in principle, yet the time occupied, and the difficulty of removing the greatly disintegrated cellular substance, offer almost insurmountable obstacles to the adoption of this method.

After the extraction of the starch from the fibrous matter of the pulp, the next operation is the separation of any particles of sand, clay, and other heavy impurities from the fecula. This is done by allowing the liquor as it passes off from the sieve to collect and repose for the space of a few hours, when the supernatant liquid is siphoned off, and the deposit agitated with its own bulk of water; the mixture is then passed over a fine sieve, by which stones, sand, and coarser impurities are removed. Three or four such repetitions with fresh water, using at each successive sifting a finer wire gauze than the preceding, complete the purification. To assist in this part of the work a mechanical agitator is employed in the large fecularies, similar to that shown in Fig. 553, and which may be elevated or lowered at pleasure by a lever handle. When such an arrangement is appended to the sieves the labor of purifying the starch is much diminished, as the various impurities are retained in the intermediate vessels.

PURIFICATION.—The several filtrations and depositions above alluded to being effected, the milky liquor is allowed to flow into large settlers, where it is left to repose for several hours, till the whole matter in suspension falls to the bottom; the clear water is then siphoned off, and the brownish layer on the surface, consisting of fibrous particles, pulp, and other substances lighter than the fecula, scraped off as clean as

possible by an iron scraper. This impure starch is agitated with fresh water, and then passed through a very fine brass wire or silk sieve, and allowed to rest for some time, till a further amount of white starch falls, when the same operation is repeated. The deposit left after the removal of the brownish light matter, is known in the French and Belgian works as *gras de féculé*. It is further purified by stirring it with fresh water, passing the mixture through a No. 90 brass-wire sieve, or one of silk cloth, conveying the milky liquid into a vat, allowing it to rest till the starch falls, then decanting and scraping the surface, and finally, if the mass be pure and of sufficient consistence, dividing it into lumps and placing these to dry, either unsupported or in a conical wire case; if it has not acquired this density it is customary to agitate it, and to run the thick semifluid mass into small perforated boxes lined with coarse cloth, such as flannel or calico.

Sometimes the purification of the fecula, deprived of its supernatant brownish deposit, is effected by washing it under a slight stream of water on an inclined table or sluice, twenty to twenty-four feet long by three feet in breadth, and declining one and a half to two inches in its whole length; the lighter matter is carried off by the water, leaving the pure fecula. Figs. 550 and 551

Fig. 550.

Fig. 551.

illustrate this arrangement; A, C, represent a portion of the first plane; D the next; and F the third; the three being placed on supports one above another to economize room. The starch being spread upon the first ledge, a stream of water in numerous small jets is delivered upon it by the pipe R; the workman agitates the surface of the layer with a brush, and the slight current carries the lighter particles forward, depositing a portion of the fecula in suspension as it proceeds, till it arrives at F, whence it falls into the canal, I, and thence into the settler, H. The purified starch is then brushed from the plane under a stream of water into the second vessel H'; and by siphoning the liquor from the vessel H into H'', the operation of laying a second batch may be proceeded with. As soon as the fecula has subsided in the tub or vat H', the water is decanted; the starch is then transferred into boxes of a conical form, perforated

to allow the water to drain away, and covered with cloth and set aside.

DESICCATION.—At this stage another operation, the *drying of the starch*, commences. It may be remarked here, however, that the large quantity of fecula which is converted into grape sugar and dextrin is not dried, but is at once acted upon in a manner which will be described at the end of this article.

During the time that the starch is allowed to drain in the lined boxes, it acquires sufficient hardness to enable it to retain the shape of the box; and as soon as this state is attained, the mould of starch is inverted upon a mass of plaster of Paris, which abstracts a further portion of the retained moisture, thereby rendering the loaf of fecula so solid as to endure being placed upon the stages of the drying-house for further desiccation. In this state the product is known as *green fecula*, and contains fully two-thirds water.

Desiccation in Free Air.—The free-air drying chamber is a large rectangular room, on either side of which are ranged, one above another, a number of horizontal shelves formed of bars of wood placed at a distance of three quarters of an inch to one inch apart, the whole being supported by upright posts, as shown in Fig. 552. A current of air is passed through the gallery by means of venetian ventilators at both sides, which admit of increasing the draught at will without permitting much dust to enter. The loaves of fecula are broken into three or four pieces, and laid on the longitudinal hurdle or bars already mentioned, on which they are permitted to remain during six or eight weeks; they are then taken, and, if necessary, reduced to powder under a wooden roller, and placed in the hot-air stove. In the construction of the latter, it is indispensable to have the arrangements such that the heat may be entirely under control; for if a high temperature were to act upon the starch, the corpuscles would be swelled to bursting, and a number of gummy concretions in proportion to the extent of the change would result. Such a consequence need not be feared after the chief part of the water still retained in the starch—amounting to forty per cent.—has evaporated. Several kinds of drying stoves are used for this purpose; one being a long gallery like the preceding free-air drying chamber, closed with apertures in the front for sliding shelves, on which the starch is placed to pass inwards where the warm air circulates. The heat in these cases is obtained from cast-iron pipes passing round the walls at the base, in which the draught from a fire is conducted to the chimney; and getting thereby warm they heat the air in the interior as it passes through the compartment. Fig. 552 is a sectional view of the drying stove of LACAMBRE and PERSAC, in which the starch is exposed gradually from 60° to 212°, the highest degree of heat to which the fecula is subjected. It consists of a chamber, beneath the ground floor of which a heating apparatus consisting of a stove, A, and a system of iron pipes, b, c, d, e, f, g, h, i, leading to a chimney, is erected; and the air entering this compartment by lateral apertures passing over the heated surface of these pipes gets warmed and ascends by the opening, D, in the drying chamber, where, following the direction of the arrows, it suc-

cively passes over the inclined tables, c, c¹, c², c³, c⁴, to c⁷, and thence to the outlets—c⁹ and c¹⁰—at the top. The starch passes in an opposite direction, being intro-

Fig. 552.

duced at the door, B⁴, at the top upon the plate, c⁷, and thence it is pushed forward over the plates, c⁶, c⁵, c⁴, c³, by the aid of the working doors, B³, B², B¹, and B, till it arrives dried at c, and falls upon the ledge, c¹, into the receiver outside the wall of the chamber.

Another drying chamber constructed upon the same principle, but self-acting, consists of a chamber and heating apparatus essentially like that last described; but instead of plates inclined one towards another, there are a number of rollers fixed two and two at the same height in the interior, upon which travels an endless band of cloth, and which are sustained in the middle by cross rods of wood. By means of gearing-wheels on the ends of these rollers, the cloth of each pair is moved in an opposite direction to that immediately above it, and the whole are set in motion by the power acting upon the highest roller, e, in the chamber. All the gearing-wheels on the axles of these rollers being of the same diameter, they move with the same velocity, so that the moist starch, introduced through the door at the top and spread upon the web, is carried forward from one end of each web to the other, till it reaches the utmost limit of the lowest one. From the disposition of the rollers the fecula falls from one

cloth to another alternately at either end, and ultimately into the chamber, the heated air ascending in an opposite direction.

The fecula during the passage through these hot-air chambers loses from eight to fifteen per cent. of moisture, according as it has been more or less dried in the free-air chamber, and is now in the ordinary state for sending into the market, except when, for laundry purposes, it is mixed with a certain amount of coloring matter, such as smalt blue and the like, or sometimes of late with incombustible matters, to secure fine light dresses from being so prone to ignition. Fig. 553 represents an apparatus employed for this purpose; *a* is a conical hopper in which the fecula is put, together with the smalt, indigo, or Prussian blue employed. The mixture passes through numerous holes in this funnel-shaped hopper, and falls upon the

Fig. 553.

first sifter, *b b*, through which it is urged by the revolving brushes, *d*; thence it descends to the second and finer sifter, *c c*, swept, like the other, by brushes, which accelerate the passage of the fecula into the bottom, *e*, of the vessel, and from this it runs by the tubes, *g g*, into sacks or boxes placed for its reception. The brushes are attached to a central shaft, *f*, which is turned by the gearing-wheels in connection with an engine, or other motive power. Sometimes the slight coloration which is given to laundry starch, as sold by grocers generally, is communicated immediately after the first desiccation in the free-air chamber; and the moisture is driven off afterwards in the drying stove.

RICE STARCH.—Within the last twenty years the extraction of starch from rice has received considerable attention in England; and is now extensively practised. It will be seen from the results stated at page 950, that this grain contains more starch in proportion to its other constituents than any other; the gluten, however, is so minutely divided in it that its separation was impossible by the old system of fermentation, and this accounts for the preference so long given to wheat and flour. By the partial use of chemical agents

this difficulty has been overcome, and rice is now extensively employed for the manufacture of starch. Among the several patent processes introduced for this purpose are those of JONES, BERGER, BIERLEY, REHE, and others, who employ either an alkali or an acid for the solution of the gluten.

JONES directs that the rice be steeped in a solution of caustic potassa or soda, containing two hundred grains of alkali to the gallon, using fifty gallons of such lie to one hundred pounds of rice; the mixture is well stirred, and then allowed to digest for twenty-four hours; after which the lie is siphoned off as much as possible, and the grain is washed with twice as much pure water as the liquor drawn over. The grain is then placed upon a drainer, after which it is crushed or ground between stones or rollers, and the coarse flour sifted in an apparatus furnished with brushes. That which refuses to pass through is returned to the mill with a fresh portion of prepared grain, and this process is repeated until the whole, with the exception of the husk, is made to pass through the sieve. The meal thus obtained is treated with a further quantity of the alkaline liquid, the proportions being one hundred gallons to a hundred pounds of the meal, and the action is quickened by frequent agitation of the mass during twenty-four hours; after which it is allowed to repose seventy hours. During this period there is first a deposit of fibrous matter with a little starch; then the starch falls, the chief portion of the gluten, with some other bodies, being retained in solution by the liquor, which is removed by a siphon without disturbing the separated matter. Double the previous quantity of pure water is now poured on the starch, the whole being well agitated, and allowed to rest for an hour, to permit the heavy substances other than starch to fall to the bottom; this done, the milky liquor containing the chief portion of the pure material is drawn over into another vessel, being passed in its course through wire or cloth sieves. A further quantity of water is used to wash the deposited matter, which, being agitated with the liquor as before, the whole is left to rest; and after the crude impurities have fallen, the starchy menstruum is again drawn off. By repeating these operations as often as may be necessary, the separation of the starch is completed; and the fine silk or brass-wire sieves detain any fragments of husk, so that the substance is well purified. All the successive liquors being added to the first, the whole is stirred and then left to settle for seventy hours; after this time if the whole of the starch has subsided, the clear supernatant liquor is drawn off, the deposit is mixed with the necessary quantity of coloring matter, and then treated in the usual way by boxing, draining, and desiccating.

BERGER's process is analogous to that just described; a hundredweight of the rice is steeped during two days, then removed from the water, and after being drained, is crushed or ground to meal, among which as much water is introduced as to give it the consistency of thick cream; in this condition it is passed through a sixty-holed sieve, returning what is too coarse to be further ground. The filtered or sifted mass is now stirred with a solution of seven pounds and a half of carbonate of soda in three and a half

gallons of water; and when the whole has been thoroughly blended, it is allowed to rest during four hours, then agitated again, and the operation repeated at equal intervals till the contact has been prolonged to about sixty hours. After this it is suffered to rest eighteen hours, and at the end of that time the lie containing the chief portion of the albumen is drawn off. A second treatment with a similar lie is succeeded by a washing with large quantities of water, and after allowing the heavy particles to fall, the milky liquor is passed through fine sieves, and the starch further purified by the inclined plane, or by repeated washings and depositions.

By another process, likewise patented, BERGER proposed to prepare the starch of rice by fermentation, the chief feature of which is the steeping of the grain in water for successive periods of four to six days, then grinding in the usual way, and repeating the steeping until the entire gluten has been so far altered by fermentation as to be taken up by the several liquors; the starch is afterwards finished by siftings, washings, *et cetera*.

COLEMAN, in 1841, patented the following method of preparing rice starch by fermentation:—The rice is steeped during five or six days, then drained from the water, and ground in the usual way; the meal reduced to a pulp is mixed in the recipient with a quantity of the refuse of wheat, or other fibrous matter, in the proportion of fifteen pounds of the latter to the hundredweight of rice, and a sufficient quantity of water is added to reduce the whole to a homogeneous mass, which is allowed to rest during ten to fifteen days. The patentee states that by this time the starch will have separated, and may be purified in the ordinary way by washing and sifting.

Another mode for preparing rice starch by the agency of acids is thus described:—The substance after being steeped for four days is drained, and then reduced to a pulp in a mill under a stream of water, which carries it off to a reservoir, where it is allowed to settle, and the water is then separated by a siphon or plug-hole in the vessel. The deposit is then agitated with an acid liquor prepared by adding three quarters or one ounce of ordinary hydrochloric acid with two pounds of rice to the gallon, stirring well the whole mass, and leaving it to stand during five days with agitation at intervals of four hours; finally, eighteen hours are allowed for the substance to deposit, after which time the clear liquor is drawn off, and the operation repeated with a second acid liquor three-fourths of the strength of that first used. When the period mentioned for the final deposition of the starchy mass has transpired, the acid liquor is drawn off as before, and the residue washed with large quantities of water, passing it through sieves as usual to separate the husk and other impurities which may still remain, and finally the mass is drained and dried in the ordinary way.

REHE took out another patent for a method for preparing rice starch, the chief feature of which is, that he submits the rice at first to a temperature of 160° to 180° before steeping; and after the matter is levigated, he employs a stronger alkaline lie—four pounds of soda to a hundredweight of rice—for washing the pulp.

In the subsequent washings, *et cetera*, the treatment prescribed by the patentee is similar to those already mentioned.

RAINSFORD employs hydraulic pressure in conjunction with alkali to extract the fibrinous matter from the rice before grinding, and finishes the product by further treatment with alkaline-water washings, siftings, and the like; he uses pressure also to expedite the operation of expelling the last portions of water from the finished starch.

MAIZE OR INDIAN CORN STARCH.—Of late years maize has been used for the manufacture of starch, and has been found to answer the purpose very well, containing as it does a large per centage of that substance. The principal makers are POLSON and BROWN of Paisley, Scotland, who employ a process patented by the former in 1854. By this method the grain is first steeped either in an alkaline water of the usual strength, or in water only, till thoroughly soaked; it is then levigated in the ordinary way either by rollers or a mill, and the pulp is passed over a sieve, through which the finer portions are forced by revolving brushes, whilst the coarse matter is returned to the mill to be further levigated, and is then sifted again. In this way most of the husk is separated from the flour or starchy portion of the grain, and is economized as cattle food. A stream of water passes in upon the sifting machine, and carries the portion passing through the sieves over an inclined plane, or *run*, the breadth and length of which are proportioned to the work to be performed. In its course the heavier starchy matters subside, and the lighter fibrous substances are carried forward by the stream till they are thrown off. The plane is divided by dams, or pieces of wood laid across it, which intercept the deposited starch, until it accumulates in quantities convenient for removal. Most of the glutinous or fibrinous matter and husk is thus separated, and a starch is obtained which, though not entirely free from nitrogenous and fibrous matter, answers well for ordinary coarse work, having high stiffening powers. It has also been introduced by that firm as an article of diet, and meets with extensive patronage. When a finer kind of starch is to be prepared, the deposit from the plane is treated with an alkaline liquid, by which the gluten is dissolved; and by sifting through a finer texture, washing on the plane, and the other usual manipulations, the starch is obtained perfectly pure.

WATT of Belfast is also patentee of a process for preparing starch from maize, and which in its chief features is similar to the foregoing, with the exception that WATT steeps the grain in repeated changes of water, or in a current, till incipient fermentation takes place, the water being in either case heated between 70° and 140°; after which the matter is drained and ground as usual, with the necessary quantity of water, likewise heated, to reduce it to a creamy consistence. This is then sifted with the aid of brushes, and the coarser portions returned, if necessary, to be again levigated, *et cetera*. The sifted matter is washed and purified either by the inclined plane or in vats, as in the preceding methods.

STARCH FROM MILLET.—A process patented by RICKETT for the extraction of starch from millet,

especially from that kind known as *Dari*, embraces the usual series of operations, namely, steeping, grinding, sifting, and treatment with alkalies, alkaline carbonates, or acids, such as hydrochloric or acetic acids, washing and finishing in the manner already detailed.

STARCH FROM HORSE-CHESTNUT.—HEDENUS and FLAUDIN have proposed to extract starch from the horse-chestnut, in which it is stated to be contained to the extent of twenty-five per cent. The chestnuts are steeped in boiling water, then skinned and grated; the pulp well mixed with soda in the proportion of one per cent. of the chestnuts operated upon; and, after a certain time, the starch is obtained by washing the mass in the ordinary way. The alkali, it is said, thoroughly removes the bitter principle of the nut.—*Richardson and Ronalds.*

ARROW-ROOT STARCH.—This starch, so named from its virtue, as formerly supposed, of curing wounds from poisoned arrows, is extracted from the roots of plants of the *Marantaceæ* of LINDLEY, more especially from those of the *Maranta arundinacea* and *M. Indica*, natives both of the East and West Indies. There are also other plants which afford a starch, designated by the same title and the name of the locality of its production. Such is the Portland arrow-root, extracted from the *Arum maculatum* of the order *Aroideæ*; the Brazilian arrow-root, from the *Jatropha manihot* of the order *Euphorbiaceæ*; East Indian arrow-root, from tubers of the *Curcuma augustifolia* of the order *Zingiberaceæ*; and Tahiti arrow-root, or tacca starch, from the roots *Tacca oceanica* of the order *Taccaceæ*, with many others. Arrow-root is a snow-white powder, and is very much prized as a dietary article, though its estimation in this respect has now considerably diminished. The starch which is contained in cells in the joints of the rhizome or underground stem, is extracted in Jamaica, as PEREIRA states, in the following manner:—The tubers, when about ten or twelve months old, are dug up, well washed in water, and then beaten to a pulp in large, deep, wooden mortars; this pulp is thrown into a large tub of clean water, well stirred, the matter strained, the residuary pulp expressed and thrown away. The milky liquid thus obtained is passed through a cloth or hair sieve, allowed to settle, and the clear supernatant liquid drained off. More clean water is poured on the white deposit, the whole stirred; and, after the deposition of the solid matter, it is drawn off as before. Finally, the deposit is drained and dried on sheets in the sun, when it is fit for commerce.

In Bermuda, and in the Island of St. Vincent, the tubers are carefully deprived of their paper-like scale, as this is said to contain a resinous matter which imparts both a color and a disagreeable flavor to the starch; they are then rasped by a machine, or ground by a mill, and the meal being well washed with pure water through various forms of sieves is ultimately dried. To insure greater purity of the product, URE states that the vessels and cylindrical sieves employed on many of the estates, are constructed of tinned copper; that the scrapers used to remove extraneous matter from the deposit, as well as the shovels with

which it is packed in bags, are made of German silver; and that whilst drying, it is protected from dust and insects by a veil of white gauze.

A method similar to that first stated is followed in the East Indies, for extracting the starch from the roots of the same plant, as well as from the *Curcuma augustifolia*, the product of which is distinguished as curcuma starch, or *tikor*, imported from Calcutta. There are two varieties of the latter, the white and the buff-colored *tikor*, or East India arrow-root, and which can be readily distinguished from the West Indian product, both by its physical properties and by its appearance under the microscope. PEREIRA states that the white *tikor* appears to the eye to resemble a finely-powdered salt, such as bicarbonate of soda; that when pinched or pressed by the fingers, it wants the firmness so characteristic of the West Indian arrow-root. The form of the granules under the microscope he states to be different, the curcuma starch being transparent flattened disks of an ovate, or oblong-ovate shape, having a very short neck, or nipple projection, at one extremity where the hilum is situated; and, owing to the flatness of the grains, they have but little lateral shading, except when viewed edgewise, the lines forming only segments of circles. Both these kinds are used for food, like the West Indian product, to which, however, they are deemed much inferior. Portland arrow-root, or Portland sago, so named from being imported from the island of that name, is prepared much in the same way as the foregoing, namely, by scraping the tubers of the *Arum maculatum*, pounding or rasping them in a mortar or machine, washing with water, straining, *et cetera*. It is a white amylaceous powder composed of exceedingly small granules of a circular, muller-shaped, or polyhedral form, having a hilum in a central depression in the grain. This article is likewise used as a dietary.

CASSAVA STARCH.—Known also as tapioca meal and Brazilian arrow-root, is obtained from the roots of the *Jatropha manihot*, a native of Brazil. The roots contain a powerful acrid poison which is readily extracted by water and destroyed by heat, so that, in the course of the preparation of the starch—a process similar to those already described—the poison is entirely separated. It is imported into England from Rio Janeiro, and appears as a white pulverulent substance resembling the genuine arrow-root. Under the microscope the difference is seen at once, this starch being somewhat similar to the Portland arrow-root in the shape of the granules, though much smaller; the hilum circular and surrounded with rings.

Tapioca.—This substance is the meal from the roots of the above-mentioned plant, scraped, washed, and rasped into flour. Whilst still moist it is dried upon hot plates, by which treatment some of the starch grains swell to bursting, and the amylaceous matter thus liberated cements the whole into small irregular masses. Hence tapioca is partially soluble in water. In boiling water it swells up and constitutes a transparent jelly-like mass.

Tahiti or Otaheite arrow-root is obtained from the tubers of the *Tacca oceanica* and *pinnatifida*, a native of Tahiti and other South Sea islands. It is imported

into London, and sold under the title of *arrow-root prepared by the native converts at the missionary stations in the South Sea islands*. The tuberous roots, which yield a highly nutritious fecula, are washed and scraped to remove the outer skin, then reduced to a pulp by rubbing on a kind of rasp made by wrapping coarse twine from the cocoa-nut fibre tightly round a board, or, as ELLIS states, on a piece of coral; the pulp is then washed with sea-water on a sieve made of the fibrous web that protects the young frond of the cocoa-nut palm. After the deposition of the fecula the liquor is drained off, the sediment made into balls and dried in the sun from twelve to twenty-four hours, then broken up, and the desiccation finished in the sun. This starch has a slight musty odor, though in color it resembles genuine arrow-root. Its particles appear smaller than cassava starch; they are circular, muller-shaped, and polyhedral, having a small circular hilum, and but few and not very distinct rings.

There are a great many other tropical plants from which starch could be extracted, such as the unripe fruit of the plantain and banana, and the tuber of the *dioscorea* or yam, the former of which is stated to afford seventeen per cent. of starch, and the latter nearly twenty-three per cent.

Tous-les-mois.—The starch or fecula bearing this name is allied to the preceding. It is extracted from the tubers of the *Canna edulis*, a native of the West Indies. The seat of its manufacture is principally St. Kitts, whence it was introduced into England in 1836. From the account of Mr. WORDSWORTH, it appears that the plant grows to the height of four feet or more, and yields a tuber three or four times as large as average-sized potatoes. The fecula is extracted to the amount of twelve and a half per cent. of the tubers by rasping and subsequent washings in the ordinary way. Its granules are much larger than any other kind of starch, not excepting that of the potato; and consequently it may be readily distinguished from the latter by the practised microscopist. In bulk it has a satiny, glistening appearance, somewhat resembling potato starch, but devoid of the dead white of the genuine arrow-root.

PEREIRA gives the following as the principal distinguishing characteristics of this and potato fecula:—

1. The particles of potato starch are smaller and more irregular in size than those of *tous-les-mois*.

2. The larger particles of potato starch are more irregular in shape than those of *tous-les-mois*: the latter are more constantly rounded-oblong, or ovate-oblong; the former more oval, often approximating to the shape of an oyster or muscle shell, or a triangle with rounded corners, and frequently gibbous or tumid at different parts of their surface.

3. The rings seen on particles of *tous-les-mois* are fine, regular, uniform, concentric, and crowded; those of potato starch are coarser, irregular, often eccentric, irregularly drawn out, distorted, or more and unequally distant from each other. In potato starch a greater number of complete rings are visible, and may be traced round the hilum even in case of many of the larger rings. With *tous-les-mois* only a few of the smaller rings can be thus distinguished.

4. The hilum is situated nearer to the end of the corpuscle in the *tous-les-mois* than that of fecula.

Lastly, When viewed with polarized light the cross is generally less regular in the potato starch grains than in those of the *tous-les-mois*.—*Pereira*.

SAGO.—This is the title of a starch extracted from several varieties of palms very common in Sumatra, Borneo, and other islands of the Indian Archipelago; the word is derived from the Malay name, *sagu*, for the palm and the farina itself. The genuine sago is imported into England from Singapore in large quantities, but a fictitious kind is made at home in many of the starch manufactories from fecula and wheat starch. The real plant which affords the sago is still undefined, for several of the species are known to yield it, those of the *Sagus* and *Sagurus* being the most important. The *Sagus rumphii*, *Sagus inermis*, *Metroxylon sagus*—the *rambija* of the Malays—*Corijota urens*, or sago palm of Assam, *Borassus gomuto*, and a few others are the most resorted to, together with several species of *Zamia*, *Corypha*, and *Mauritia*. In most of these trees the pith is so abundant as to constitute a great part of the bulk of the entire stem, which from its rapid growth often attains to a thickness of a foot or more in diameter in the course of six or seven years. From such a tree it is stated that as much as three hundred-weight of sago can be obtained.

The method adopted for extracting the medullary matter from the tree and separating the starch from it is somewhat different from that followed in preparing arrow-root starch; but the mode of preparing the sago bears so much resemblance to the European system of preparing grain starch, that it will be unnecessary to enlarge upon it in detail. In the Moluccas, the tree when sufficiently matured is cut down near the root, and then divided into portions averaging seven or eight feet in length, which are split open and the pith extracted. By various means—such as pounding in a mortar, *et cetera*—this substance is reduced to a coarse powder, which is agitated with water and submitted to the usual siftings and washings; the farina is then allowed to deposit, and on drawing off the fluid and drying the residue, the *raw sago meal* is obtained. From this the granulated and pearl sago is prepared, after submitting it to a bleaching process preparatory to granulation. To bleach it, the sago meal or flour, mixed with water to the consistence of cream, is exposed in close vessels to the agency of sulphurous acid or chlorine, or to a solution of hypochlorite of lime or soda, and afterwards well washed; a little sulphuric acid being mixed with the washing water when the hypochlorite is used.

In New Guinea the granulation is performed by making a paste of the sago meal with water, and passing this through a sieve into a very shallow iron pot placed over a fire. The particles on being heated assume a globular form. BLUME states that the same method is followed in Singapore by the Chinese, only that during the heating the particles are constantly stirred and turned; he adds, that though the material is quite white at the commencement, it gets hard and somewhat pellucid during the process. PEREIRA says that the tapioca sago of GUIBORT is submitted to the

action of heat, but so well managed is the operation, that none of the substance is in the least charred. He adds that some of the sago of the shops presents no appearance of having been heated, and in this case it is supposed that the granulation is effected by a mill. Two kinds of granulated sago are known in commerce—the common brown or red, and the white or pearl sago. The color is attributed by PLANCHE to the red matter contained in the variety of palms from which the starch is extracted, and by the application of the heat required for granulation altered to a grey, which is the usual color of unrefined sago. Formerly the imported article presented a great inequality of aggregation, varying from very small grains to that of pearl barley or peas, the substance being, however, identical in both, and evidently composed of cemented particles of sago meal. Pearl sago dates from a recent period; CRAUFORD, whose account of it was the first published, states that the method of manufacturing it was discovered by the Chinese of Malacca, a few years previous to 1820, the year in which he wrote. It is met with in pearl-like grains of an irregularly globular form, ranging from the size of a poppy to that of white mustard seed or a little larger. The surface of the larger grains is generally smooth and even, but that of the smaller kinds is uneven and somewhat tuberculated. Under the microscope, the particles of this variety present the same appearance as that of the colored product and sago meal, except that the most of them appear ruptured from the action of the heat. Sago when granulated possesses the property of considerably swelling in hot water or other liquids, without losing its adhesive power; hence the grains appear translucent and gelatinous, but not as slimy globules. The following table by PLANCHE exhibits the quantity of water which the different varieties of sago met with in commerce take up in softening, as also the chief distinctions of the farina itself:—

Source.	Color.	Water absorbed in softening, Per cent.
Maldines,....	Grains, mostly red, some white,...	150
Sumatra,....	Grains, white or dirty-white,....	134
New Guinea,	Grains, brick-red or lighter,....	121
Moluccas,....	Red variety,.....	130
Do.,	Grey,.....	109
Do.,	White,.....	164

Of late years, more especially in Germany and France, considerable quantities of artificial or fictitious sago have been manufactured from inferior starches, such as fecula. The process is simple, consisting merely of submitting the starch after air-drying to a temperature of 212° on iron plates, and thus causing the granules to swell to such a degree that some of them burst, when the gummy matter forms a cement that envelopes other granules. Care must be taken that the heat does not rise so high as to discolor the matter by partial charring, which would be highly detrimental. After the heating the mass is passed through a mill, or sifting and rolling machine, by which it is reduced to the globular form of pearl sago. When dry wheat or potato starches are operated upon, a previous moistening is necessary in order to incorporate as much water as will facilitate the swelling and fracturing of the granules at the comparatively low heat necessary to insure its cementation.

DERIVATIVE PRODUCTS FROM STARCH.—Two products are obtained from starch which are very extensively employed, not only by themselves, but also for the production of other substances of considerable importance. These are *dextrin* and *glucose*, of each of which it will be necessary to give a short account.

Dextrin.—This substance has been briefly described under the term BRITISH GUM in Vol. II., page 313; but its importance deserves that some further details should be given here. It is a substance immediately produced from, and isomeric with starch, and is so called from its property of diverting to the right a ray of polarized light transmitted through its solution. It is soluble in water and in dilute spirit of wine, but insoluble in absolute alcohol. A solution of iodine does not alter its color in solution, except when the transformation of the starch is incomplete, in which case it produces a violet, shading off to a red tint. When the colorless solution of this substance in hot or cold water is evaporated, a viscous mass is obtained, which, on being dried, yields the dextrin in a mass somewhat resembling gum-arabic; it is similar also in its properties, so much so that in many applications it is substituted for gum-arabic at a great saving; and hence the trade that has sprung up of late years in this substance under the title of British gum, *leïocomme*, *et cetera*. It does not, however, like gum-arabic, yield derivatives, such as mucic acid and the like, when treated with nitric acid and other agents, and in this respect a marked chemical distinction is established between the two substances. On the methods resorted to for its preparation, the Editor has nothing to add to the details given at the page above referred to.

Glucose.—In starch factories, especially on the Continent, a considerable quantity of starch or potato fecula is converted into glucose—a species of sugar which is found in many kinds of fruit, especially the grape, and into which all other varieties of sugar, whether it be the product of the cane, maple, or beet, is readily resolved by the action of acids and other chemical agents. The chief use to which glucose is applied on the Continent is for the manufacture of beer, and a coarse kind of alcohol, which is said to be extensively converted into French brandy by the addition of oil of raisins, coloring matter, *et cetera*. There are two methods by which the starch; or rather dextrin, is converted into glucose; the one is well exemplified in all the breweries and distilleries of the kingdom, where thousands of tons are annually formed in the preliminary stages of malting and mashing; the other consists in the use of sulphuric acid, which is a more expeditious method, and gives a purer product than when the conversion is effected by means of diastase. The process is naturally divided into six stages, namely, the conversion of the starch into dextrin, the saccharification of the dextrin, the settling of the liquid, the evaporation, the filtration, and the concentration. PAYEN describes the apparatus and operations connected with it as follows:—

The saccharification of the starch is effected in large tubs or vats, A A'—Fig. 553—constructed of stout wood, to contain two thousand eight hundred gallons. In one of these, A', a lead pipe, *b c d*, coiled at the bottom, is placed, the circular portion being cut or

perforated for the introduction of steam to heat the acidulous water with which it is two-thirds filled; the steam from the generator, *i*, is admitted to it at plea-

sure by means of the pipe, *b f e g*, and stopcock, *h*. During the operation the vat is covered, and the disengaged vapor conducted to the chimney, *B D*; but

Fig. 553.

before escaping it may be utilized in evaporating the sirup by conveying it through serpentine pipes, *E*, *F*. By such arrangements the disagreeable odors resulting from the evaporation of the oil of the starch are considerably abated, being partly condensed in the serpentine pipe, so as to flow off with the water produced from the steam into a vessel interposed between the pipes, *F*, *G*, and partly carried away by the pipe, *F'*, *F''*; or the uncondensed vapors may be conducted into the fire where any remaining traces of essential oil are consumed, and thereby the nuisance is almost entirely prevented.

When it is proposed to convert two tons of fecula in such an apparatus, the substance is suspended in portions of two hundredweight in a trough or tub, with twenty-two gallons of water, and when thoroughly steeped, it is introduced by a funnel, *a*, in quantities of four to five gallons at a time, into the large tub or vat, which should be previously charged with about thirty-two barrels of water, and three quarters of a hundred of sulphuric acid agitated with it, the whole being raised to 212° by forcing steam into it. This temperature is maintained till all the fecula is introduced, and it is found that the transformation is accomplished in thirty or forty minutes after the last portion of the starch has been added. The point at which the change is completed is easily ascertained by simply testing a few drops of the clear liquid with a drop of a solution of iodine, when, if the saccharification be effected, no coloration takes place; in the contrary case the cha-

racteristic violet of iodide of starch manifests itself. After the conversion into glucose, the introduction of the steam is suspended, and the next operation is the saturation of the free acid by means of carbonate of lime, and the consequent precipitation of sulphate of lime. The latter being but sparingly soluble, most of it falls to the bottom. It requires from ninety to a hundred pounds of chalk to saturate the whole of the free acid; and this must be introduced gradually to guard against the evolution of too much carbonic acid at once. If an excess of lime be used, it prevents the solution from clarifying so readily as when the sulphuric acid is barely taken up; this is shown by the cessation of effervescence, and the inability of the liquid to change the blue color of litmus to more than a feeble purple tint. When the saturation is completed, the mixture is either permitted to repose in the same vessel, or if it be required to operate upon another batch at once, it is drawn off into the lower vat *A''*, where it is left at rest during twelve hours; the clear liquid is then racked through coarse bone black in the filters, *H*, *H*, the deposit of sulphate of lime being also thrown upon cloth filters, where it is drained and washed. The sirup as it flows off from the filter, having a density of 1.11 to 1.122, is retained in the reservoirs, *L*, *L*, *L*, from which it is raised by a pump or a chain of buckets to the reservoir *M*; from this it is distributed in a horizontal channel, *m*, by numerous lateral apertures upon the serpentine evaporator, *E*, *F*, and then flows by a channel, *p*, and tube, *q*, into

a receiver, *r*, whence it can be drawn at will by the tube, *s*, and stopcocks, *n, n*, into the boilers, *P, P'*, which are heated by steam, and in which the liquid is concentrated to 1.26 specific gravity. The sirup thus obtained, after reposing a sufficient time to allow the sulphate of lime precipitated by the evaporation to subside, is fit for the brewer or distiller; but if intended for the confectioner or liqueur-maker it should be allowed to rest for twenty-four hours, filtered when cold through coarse bone black, and casked immediately. When it is desired to obtain the glucose in a solid state, the evaporation is carried so far as to concentrate the sirup to 1.38 or 1.39 specific gravity—73° to 74° Twaddell; it is then poured into the cooler, where it is left till the crystallization commences, and thence transferred to the tuns in which the solidification is effected.

Of late years, instead of preparing the sugar in an amorphous solid mass, as by the preceding method, it is obtained in grains or regular crystals. The process for converting the starch into sugar is the same as that already described; but care is taken to do it more thoroughly, since any excess of dextrin in the sirup is found to prevent crystallization. After the acid has been neutralized, and the lime salt removed by deposition, *et cetera*, the saccharine liquid is decolorized, and concentrated to 1.300, or 60° Twaddell, in summer; and 1.262 or 53.5° Twaddell, in winter. At these stages it is racked off into large reservoirs where the lime salts settle down; and during this period it is necessary, in order to prevent any fermentation, that the liquid be cooled either by circulation of air or of cold water in a coil placed in the vessel. After thirty-six to forty hours, the sirup, being clarified and cooled to about 65°, is put to crystallize in ordinary tuns furnished with a false bottom placed over the lower one, which is pierced with a number of holes that are stopped with wooden pegs. These tuns are placed on stages along the walls of the room, twelve to fifteen inches above the floor. A sheet of lead, or large canal or sluice, reaches along each range of crystallizing tuns. To avoid the fermentation of the sirup, which in summer often prevents the crystallization, six or seven ounces of sulphurous acid solution are added to the content of each tun. At the end of eight or ten days the crystallization commences and goes on, the crystals depositing in succession. When the bulk of two-thirds of the liquid becomes a mass of crystals, the pegs in the lower bottom are withdrawn, and the still fluid portion is permitted to drain off, the operation being quickened towards the end by tilting two adjoining tuns against one another. The drainings are conducted to the converting tun, where any dextrin the liquor may still contain is saccharified.

The desiccation of the drained sugar was long a work of difficulty, the moisture of the air being sometimes sufficient to convert it again to sirup, which, with the heat of the factory, melted and agglomerated the remaining portion. M. FOUCHARD has obviated these inconveniences by furnishing the tuns or tubs, *R R*, with tables of plaster of Paris, which absorb the portion of the interposed sirup. This very much quickens the desiccation of the crystals, especially in

a current of air heated to 77°, taking care that the granules are not thereby soldered together. There is, however, a certain amount of the crystallized mass which has to be submitted to a second solution, namely, that which is agglomerated on the end of the loaf resting on the plaster; this must be separated, and the sugar extracted from the sulphate of lime, by grinding them between cast-iron cylinders, and dissolving in the ordinary way.—*Payen*.

Glucose crystallizes in grains formed of a number of lamellar plates radiating from a common centre, and thus forming a kind of bristling spheroid of lamellar points. It has only one-third the sweetening power of cane sugar, whilst it is once and a half less soluble; at 212° it melts in its water of crystallization, which characteristic allows of its recognition when in certain proportions in cane sugar. It may also be detected by the property which glucose possesses of forming definite compounds with alkaline and earthy bases, which compounds suffer decomposition, and become strongly colored brownish, at a temperature between 160° and 212°, which is not the case with cane sugar under like circumstances.

Glucose is composed of $C_{12}H_{12}O_{12}$, 2HO, differing from starch, $C_{12}H_{10}O_{10}$, only by an addition of two equivalents of the elements of water, and two equivalents of the water of crystallization, with which, however, it parts when carefully exsiccated, leaving the compound of the composition $C_{12}H_{12}O_{12}$.

STRONTIUM.—Although less abundantly diffused, it resembles barium both in its chemical and geological relations. Like it strontium is never found native, but only as *carbonate* and *sulphate*. It was first recognized by HOPE in 1792, in the mineral *strontianite*, so called from Strontian in Scotland.

Pure strontium was first made by BUNSEN and MATTHIESSEN in 1855; impure by DAVY in 1807. It is prepared by electrolysis from chloride of strontium. It is a golden-yellow metal, of considerable metallic lustre, harder than lead, and ductile. It melts at a red heat. Heated in air, it inflames and burns with a bright lustre in oxide. In dry air it remains untarnished; but it decomposes water, even at ordinary temperatures, with singular vehemence. Fuming nitric acid does not attack it; but dilute acids oxidize it readily. It burns in chlorine, iodine, bromine, and sulphur atmospheres, producing the corresponding compounds. Strontium has a specific gravity of 2.542, and an equivalent weight of 44. It is only in a strictly scientific light that this metal and its compounds are of any importance, excepting the chloride and nitrate, which are much used by pyrotechnists. The chemical symbol of the metal is Sr.

A few of its principal compounds are briefly described in the following:—

OXIDE OF STRONTIUM.—*Strontia*.—This base is most easily obtained by igniting the nitrate. It is greyish-white, and of specific gravity 3.932. It is neither fusible nor volatile. For water it shows powerful affinity, and forms a *hydrate*. This is soluble in fifty times its weight of cold, and 2.4 parts of boiling water. From the latter it separates in crystals belonging to the square prismatic system. Nine equivalents

of water are easily expelled by heat; but it requires a temperature approaching white heat again to render the hydrate anhydrous. Both strontia and its hydrate readily absorb carbonic acid. The symbol of strontia is SrO , and the equivalent 52; the symbol of the hydrate is $\text{SrO}, 9 \text{HO}$.

CARBONATE OF STRONTIA is found native as strontianite, both massive, and in forms belonging to the square prismatic system. It is most readily prepared pure by precipitating the nitrate or chloride with carbonate of ammonia. The artificial carbonate is beautifully white and soluble in one thousand five hundred and thirty-six parts of boiling water. It is more soluble in aqueous solution of carbonic acid, and separates in needles when evaporated. Heated to bright redness in a stream of watery vapor it loses its carbonic acid, and becomes changed into strontia. The symbol is SrO, CO_2 ; Eq. 74.00; specific gravity, 3.605.

SULPHATE OF STRONTIA is the *celestine* of mineralogists. Sometimes massive, it is often found beautifully crystallized in prisms isomorphous with sulphate of baryta. Artificially it may be prepared by precipitation from any of its soluble salts, either by sulphuric acid or a soluble sulphate. It has the form of a white tasteless powder, soluble in fifteen thousand parts of cold, and three thousand eight hundred and forty parts of boiling water. In solutions of common salt it is slowly but completely soluble. A solution of sulphate of strontia precipitates salts of baryta. The symbol is SrO, SO_3 ; Eq. 92.00; specific gravity, 3.95.

NITRATE OF STRONTIA separates from concentrated solutions in transparent colorless octohedra, soluble in five parts of cold, and half their weight of boiling water; insoluble in alcohol. It has a sharp, cooling taste, and decrepitates in the fire, leaving strontia. At low temperatures it crystallizes out from more dilute solutions with five equivalents of water. Nitrate of strontia is much used by pyrotechnists to produce a splendid crimson flame. A mixture of forty parts of the nitrate, five of chlorate of potassa, thirteen of sulphur, and four of the sesquisulphide of antimony, is found a good one in practice, but *great care* is necessary in the admixture. The symbol is SrO, NO_3 ; Eq. 106.00; specific gravity, 2.704.

On the large scale the nitrate is prepared by heating pounded celestine with one-third of its weight of bituminous coal, dissolving the resulting sulphide in water, and decomposing with dilute nitric acid.

CHLORIDE OF STRONTIUM is in long, six-sided needles, deliquescent in moist air, and soluble in three-quarter parts of cold water. It imparts an intense crimson color to flame. In alcohol it is also soluble. When heated, the chloride melts and becomes speedily anhydrous. Ignited in air, it loses chlorine and absorbs oxygen. The chloride of strontium is most easily prepared by dissolving the sulphide in water, and decomposing with hydrochloric acid. The symbol for the salt is $\text{SrCl}, 6 \text{HO}$.

General Character of the Salts of Strontia.—They are colorless; not poisonous, like most of those of barium. Before the blowpipe they communicate a crimson color to flame. Neither hydrofluosilicic acid nor

hyposulphite of soda precipitates them. The chromate of strontia is sufficiently soluble to be employed as a test for baryta; but oxalic acid produces immediate turbidity in them. On addition of sulphate of lime to a solution of a salt of strontia, there arises gradually a white precipitate of sulphate of strontia; immediately when heated.

Strontia is always determined in analysis as sulphate or carbonate; one hundred parts of the former contain 56.52 of strontia, and of the latter 70.27 parts of this base.

SUGAR.—*Sucre*, French; *Zucker*, German; *Saccharum*, Latin.—Sugar seems to come more directly from the Persian *Shukkur*, which is nearly the same as the English pronunciation. The Arabic name is similar, and the probable origin of both is said to be the Sanscrit *Sarkara*. In the old Assyrian and Phœnician languages there was no letter *k*, but both nations called the substance *suicar* or *suicra*. It is said by HUMBOLDT to have been known in very early times in China. It is probable that in early historic times it was brought as a luxury and a curiosity into Western Asia and Europe. The Hebrew word for being intoxicated is *Shacar*, and strong drink *Shecar*. These words were believed to have an intimate connection with sugar; but this could only occur in a country where sugar was so well known that its ready passage into alcohol was familiar. Such was not the case in Western Asia or Syria and the surrounding countries in known times, although it may have been so at an earlier period. In the Bible is mentioned *sweet calamus* two hundred and fifty shekels; and *calamus* and *cinnamon* in SOLOMON'S Song; *sweet cane* in ISAIAH, and in JEREMIAH and EZEKIEL. There is little difficulty in believing the scriptural writers to be the earliest who allude to sugar. Persons in frequent communication with the East were sure to obtain its products before the Greeks. HERODOTUS speaks of manufactured honey, supposed to mean sugar; and STRABO mentions that NEARCHUS, one of ALEXANDER'S admirals, speaks of a reed which yields honey without bees in India. THEOPHRASTUS mentions it as a honey obtained from a reed which grew in moist places in Egypt, and had a sweet root. This sweet root has been used as a proof that he did not allude to the cane. The mention of moist places also is an objection; but so many canes do grow in moist places that one readily forgives this error and others, seeing that the fact of sweet matter from a cane is so distinctly spoken of. THEOPHRASTUS speaks of honey from reeds, evidently cane sugar. ERATOSTHENES alludes to roots in India sweet to the taste even when boiled, as if it were the custom to boil them to remove the sugar. VARRO speaks of the juice of an Indian root so sweet that, when pressed out, no honey can contend with it. DIOSCORIDES says that there is a kind of honey called *saccharus* which is found in reeds in India and Arabia Felix, having the appearance of salt; but it was only used in medicine. If found in Arabia it might well have been known early in Syria. PLINY says that there is a kind of honey which collects in reeds, white like gum, and brittle to the teeth; the larger pieces about the size of a filbert, and only used in medicine. STATIUS speaks

of boiling canes in Ebosita; but that place is not known. ARRIAN mentions it as an article of Indian commerce; and ÆLIAN speaks of it as pressed from reeds on the Ganges. It is well to add that Dr. ADAM, the learned editor of Paulus Egineta, says that the saccharum of THEOPHRASTUS, DIOSCORIDES, GALEN, STRABO, and PLINY was a concretion formed on various reeds, but especially on the bamboo cane; also, that MOSES CHORENENSIS, fifth century, first mentions the boiling of canes. This may account for the bitterness and medicinal qualities mentioned by DIOSCORIDES and others. ALBERTUS AGNENSIS relates that the crusaders found sweet honeyed canes in great quantity in the meadows near Tripoli in Syria, which reeds were called Zucra. These the crusaders sucked, and were much pleased with the sweet taste of them, with which they could scarcely be satisfied. This plant is cultivated, the author states, with great labor of the husbandmen every year. At the time of harvest they bruise it when ripe in mortars, and set by the strained juice in vessels, till it is concreted in the form of snow or of white salt. This, when scraped, they mix with bread, or rub it in water, and take it as pottage; and it is to them more wholesome and pleasing than the honey of bees. The people who were engaged in the sieges of Albaria Marra and Archas, and suffered dreadful hunger, were much refreshed thereby. Again, JACOBUS DE VITRIACO mentions reeds full of honey in Syria, pressed out by a screw and concreted by fire. WILLERMUS TYRENSIS speaks of it as being an article of export from Tyre; it seems to have at that time spread over all the Levant, and in the time of the Emperor BARBAROSSA it was made in Sicily, and used both solid and as a sirup. Sugar is said to have been imported into Venice as early as 991. It was brought from Sicily and Egypt—cheaper from Sicily—in the twelfth century. In 1166 WILLIAM II. gave a mill for grinding sugar canes to the monastery of St. Bennet. It travelled into Valencia, thence to Granada and Murcia. About 1420 the Portuguese took it to Madeira and Spain, and to the Canaries. Thence, says Dr. MOSELEY, the cultivation of the sugar cane and the art of making sugar were extended by different nations of Europe to the West Indian islands and the Brazils.

In 1518 there were twenty-eight sugar works established by the Spaniards in Saint Domingo; and HAWKINS brought some of the sugar to England in 1563. Antwerp had exported it about the same time—1560. The English planters were realizing great wealth in Barbadoes in 1650, although the Portuguese supplied the most of Europe then with Brazil sugars.

The name sugar is used in the arts to denote certain substances in the vegetal and animal kingdoms, whose chief characteristics are a sweet taste and the power of undergoing, either directly or indirectly, vinous fermentation, that is, of splitting up under the influence of yeast almost wholly into carbonic acid and alcohol. Four principal kinds of sugar are known, namely, cane-sugar, so called from the fact that its chief source is the sugar cane, though it is found in large quantities in other plants, such as the stalks of maize or indian corn, the maple, birch, palm, the beet-root, carrot, turnip, and in a large number of

tropical fruits; fruit sugar is that to which acidulous fruits owe their sweetness, and hence its designation; it does not crystallize, and exists in large quantities in treacle. The third variety is called grape or starch sugar, owing to its being found in ripe fruit, such as dried raisins, figs, and the like, or from the fact that it may be produced in quantities from starch; and the fourth kind, called milk sugar, is exclusively found in the lacteal fluid of animals.

A remarkable feature in all these varieties of sugar is, that two of the three elements of which they are composed, namely, hydrogen and oxygen, are so proportioned as to constitute water, or, in other words, that they contain the same number of equivalents of these elements. This fact has led to sugars being designated *hydrates of carbon*; but from such terms it is not to be understood that the hydrogen and oxygen really exist as water, but rather that their combination, in the proportion in which they are found in the sugar admits of the expression. The composition of the different kinds of sugar varies only in the elements of one or more equivalents of water; to which fact may be attributed the readiness with which one species is changed into another, merely by the assimilation of that liquid. This feature in the composition of sugars extends to other substances not possessing the same properties, but readily convertible into particular kinds by certain chemical operations, such as the several starches, dextrin, inulin, gum, and several others. The following tabular view of the chemical composition of the sugars and a few of the above mentioned substances will at once exhibit the great analogy in composition between the two classes of bodies:—

Name.	Composition.
Cane sugar, or sucrose,	$C_{24} H_{22} O_{22} = C_{12} H_{11} O_{11}$
Fruit sugar, or fructose,	$C_{12} H_{12} O_{12} = C_{12} H_{12} O_{12}$
Starch sugar, or glucose,	$C_{12} H_{12} O_{12}, 2 HO = C_{12} H_{14} O_{14}$
Milk sugar, or lactose,	$C_{24} H_{19} O_{19}, 5 HO = C_{12} H_{12} O_{12} \times 2$
Manna sugar, or mellitose, ...	$C_{24} H_{24} O_{24}, 4 HO = C_{12} H_{14} O_{14} \times 2$
Starch and gum group.	
Starch,	$C_{12} H_{10} O_{10} = C_{12} H_{10} O_{10}$
Dextrin,	$C_{12} H_{10} O_{10} = C_{12} H_{10} O_{10}$
Inulin,	$C_{24} H_{21} O_{21} = C_{12} H_{10} O_{10} \times 2 + H O.$
Gum,	$C_{12} H_{11} O_{11} = C_{12} H_{11} O_{11}$
Cellulose,	$C_{12} H_{10} O_{10}$

From a comparison of the formulas in the foregoing table, it will be observed that the amount of carbon in the several varieties remains the same, but that the elements of water present slightly vary, and to these their distinct and diverse properties is to be attributed.

CANE-SUGAR. — *Common sugar* is manufactured chiefly from the sugar cane, but large quantities are prepared also from the sap of the maple tree and from beet-root.

Preparation.—To make pure cane-sugar the same course of operations should be followed as will be described in preparing and refining sugar, each being executed with greater care and attention; hence it will be needless to detail the process here.

Properties.—Cane-sugar when pure, as in the finest lump, has a glistening white appearance, resulting from the multifarious reflections and refractions of light from the numerous congeries of small crystals composing it. When a very concentrated solution of this substance is left to crystallize spontaneously, it forms rhomboidal prisms with dihedral summits of considerable dimensions, especially if the nuclei be transferred repeatedly to concentrated menstrua. Thus crystallized it forms the sugar candy of the shops, and appears transparent. According to PLAYFAIR and JOULE its specific gravity is 1.594. It is soluble in about one-third of its weight of cold, and in all proportions in boiling water, forming in either case transparent colorless sirups. A solution saturated with sugar at 212° deposits a part in crystals—the candy already mentioned—on cooling. If the temperature at which the saturation is effected be raised to 230°, the whole forms a concrete granular mass when allowed to cool. This is not the case when the sirup is rapidly boiled down to the same density; for then it congeals on a cold surface in a transparent amorphous mass, which on exposure becomes opaque, owing to a fibrous crystallization radiating from the surface inwardly. In this state it is ordinarily called *barley sugar*, the change from the crystalline state being due to a dimorphism caused by the heat, analogous to that which sulphur exhibits under almost similar circumstances. Continuous boiling of a weaker sirup has a like effect. The same change, from the crystallizable to the noncrystallizable modification is effected in the cold by the prolonged contact of dilute mineral acids. Noncrystallizable cane-sugar has the composition $C_{12}H_{11}O_{11}$, HO. It is gradually converted by long-continued contact with water, especially in the presence of acids, without undergoing any chemical change, into glucose or grape-sugar— $C_{12}H_{12}O_{12}$, 2 HO—a substance which crystallizes in acicular tufts. Dilute alcohol of specific gravity 0.830 takes up about a quarter of its weight of sugar. Absolute alcohol dissolves a small quantity of it at the boiling point, but deposits it again on cooling. When the crystals of candied sugar are broken, a slight phosphorescence is discernible, and a similar phenomenon is produced on rubbing two pieces of lump sugar together. Heated to 212°, no further effect is produced on crystallized cane-sugar than the expulsion of the mechanical moisture contained in its interstices. At 320° it melts; and though not decomposed, still, as PROUT remarks, several of its characteristics are destroyed. Between 320° and 350° the liquid mass becomes transparent on cooling, though, from circumstances such as those mentioned in reference to barley sugar, the transparency is destroyed after some time. At 410° it changes to an orange-yellow, afterwards to a reddish-brown hue; and if this heat be maintained, it is converted into a new acid compound of a brownish color very soluble in water—*caramel*—with the loss of three equivalents of water. If the heat be further increased, complete decomposition takes place, with evolution of inflammable gases mixed with carbonic acid, pyrogenous oils, and acetic acid; and a carbonaceous residue, forming about

a quarter of the weight of the original substance, remains.

Cane-sugar combines directly with the oxides of the alkalies and of the alkaline earths, forming with them sugarates—improperly called sometimes saccharates; and also with certain salts, particularly with chloride of sodium. The potassa and soda compounds, which are both unstable and indefinite, are obtained as sirupy liquids on adding a strong aqueous solution of the alkali to a solution of sugar in alcohol. Their compositions are—

Sugarate of baryta is formed by dissolving one part of caustic baryta in three parts of hot water, and adding the solution to a sirup containing two parts of sugar and four parts of water. A mass of crystals is thus obtained resembling boracic acid, and having the composition—

Sugarate of baryta is difficultly soluble in water, and is decomposed by almost all acids into the corresponding baryta, salt and sugar. Even the carbonic acid of the air effects this change.

There appear to be three sugarates of lime, of which however the most definite and important has the composition—

This is formed on adding milk of lime to sirup, in the proportion of two parts by weight of lime to thirteen of sugar. After filtration the sugarate of lime is precipitated by alcohol. On drying, this body appears frangible and resinous, and is very soluble in water. This compound has the rare property of being precipitated from its aqueous solution by heat, and of redissolving as it cools. The amount of lime which a sirup takes up is less according as the density of the sirup is greater. The following table constructed by PELIGOT shows this relation—

Quantity of sugar dissolved in 100 parts of water.	Density of sirup.	Density of sirup when saturated with lime.	100 parts of residuo dried at 120° contain	
			Lime.	Sugar.
40.0	1.122	1.179	21.0	79.0
37.5	1.116	1.175	20.8	79.2
35.0	1.110	1.166	20.5	79.5
32.5	1.103	1.159	20.3	79.7
30.0	1.096	1.148	20.1	79.9
27.5	1.089	1.139	19.9	80.1
25.0	1.082	1.128	19.8	80.2
22.5	1.075	1.116	19.3	80.7
20.0	1.068	1.104	18.8	81.2
17.5	1.060	1.092	18.7	81.3
15.0	1.052	1.080	18.5	81.5
12.5	1.044	1.067	18.3	81.7
10.0	1.036	1.053	18.1	81.9
7.5	1.027	1.040	16.9	83.1
5.0	1.018	1.026	15.3	84.7
2.5	1.009	1.014	13.8	86.2

The hydrated oxide of copper is dissolved by a mixture of sugar and sugarate of lime, an amorphous double sugarate of lime and copper being formed. The sugarate of lead is not strictly an analogue of the previously described metallic compounds of sugar, which are formed by the direct union of the sugar with the metallic oxide. Sugarate of lead is sugar in

which four atoms of hydrogen are replaced by four atoms of lead—

It is produced as a gelatinous precipitate on mixing an ammoniacal solution of acetate of lead with a solution of sugar. After washing with cold it is dissolved in hot water, and allowed to stand closed from the air. The compound gradually separates out as white crystals. Massicot also gradually combines with sugar, forming the same compound, water being liberated at the same time.

The chloride of sodium likewise combines directly with cane-sugar. If four parts by weight of sugar and one part of chloride of sodium be dissolved together in water, and allowed to evaporate spontaneously, the excess of sugar first crystallizes out; the mother-liquor, on further evaporation, deposits crystals which deliquesce in moist air, of the composition, according to GERHARDT, of—

GLUCOSE, or grape-sugar, occurs in raisins, currants, and other dried ripe fruits, and in flowers. It occurs also in honey and in the urine of patients affected with diabetes, accompanying in all the above cases non-crystallizable cane-sugar. It is found also in the blood, the bile, and in eggs. Both starch and cellulose are converted into glucose by digestion with dilute sulphuric acid. The substance which appears near the germinating point at the time of germination of the cereals, called diastase, or in its crude and impure form, yeast or barm, has also the power of transforming starch into grape-sugar, for there is no evidence to show that the substance which changes starch to glucose, is other than that which changes glucose into alcohol and carbonic acid.

Aqueous alcohol dissolves all these kinds of sugar, cane-sugar, grape-sugar, and noncrystallizable sugar, in proportions greater according to the degree of dilution of the alcohol. Absolute alcohol dissolves the non-crystallizable sugar alone. This behavior is made the basis of a method of assaying sugars, as will be shown further on.

For further particulars concerning the properties and composition of this substance, see article STARCH—sub-heading *Glucose*—page 962. Glucose, like *sucrose* or cane sugar, combines with the metallic oxides to form the following glucosates—

It also combines with chloride of sodium forming—

Glucose forms with sulphuric acid a copulated acid whose salts are both unstable and incompletely examined. With nitric acid a detonating compound is produced. Mannite forms with nitric acid a similar detonating body.

MANNITE— $C_{12} H_{14} O_{12}$ —called also the sugar of mushrooms, is chiefly extracted from manna, an exudation from the *Fraxinus rotundifolia*; it is also found in celery, dog's tooth, fennel, *et cetera*, and in algæ. Mannite is one of the products of the fermentation of starch and glucose; it is produced in the transformation of starch into glucose by dilute sulphuric acid. It is readily obtained from manna by boiling it with strong alcohol; on filtering and allowing the filtrate to cool, it crystallizes out, and is purified by recrystallization from alcohol. Mannite does not readily ferment. Owing to this, it may be freed from the other sugars by submitting the liquid which contains them all to fermentation, and extracting the mannite from the unfermented residue. It is supposed that the gradual loss of sweetness effected by time on wine is chiefly due to the slow transformation which the mannite they retained after the first fermentation undergoes. Direct experiments have shown that mannite does suffer such a fermentation.

Sugar of Milk— $C_{24} H_{20} O_{20}$, 2 HO—otherwise called lactine or lactose, occurs in the milk of the mammiferæ, from which it is extracted by precipitating the caseum by a dilute acid, filtering, and evaporating to dryness.

Sorbine— $C_{24} H_{24} O_{24}$ —is found in a few plants.

Mosite— $C_{24} H_{24} O_{24}$, 4 HO—occurs in the juice of flesh, it is very soluble in water; insoluble in alcohol and ether; at 212° it loses four atoms of water.

Cane-sugar, both crystallizable and noncrystallizable, and glucose, are all capable of alcoholic fermentation. But the action of the ferment is, in the first place, to transform both the former kinds of sugar into glucose or grape-sugar.—See ALCOHOL.

Testing or Estimation of Sugar.—If a watery solution contains only one of the three kinds of sugar—namely, cane-sugar, crystallizable; cane-sugar, non-crystallizable; or grape sugar, glucose; the amount of sugar may be determined from the specific gravity of the sirup. In all cases the density of the sirup is increased by an increased quantity of saccharine matter.

The following table from Dr. URE's Dictionary shows the specific gravity at 60° of solutions of crystallizable cane-sugar containing various amounts of sugar in one hundred parts by weight of the sirup:—

Sugar in one hundred parts by weight.	Specific gravity at 60°
66·666	1·3260
50·000	1·2310
40·000	1·1777
33·333	1·4400
31·250	1·1340
29·412	1·1250
26·316	1·1110
25·000	1·1045
21·740	1·0905
20·000	1·0820
16·666	1·0685
12·500	1·0500
10·000	1·0395

The subjoined more extended table has been constructed by PAYEN for a similar purpose. It shows the density at 59° of sirups formed by dissolving one hundred parts by weight of sugar in different quantities of water. The values differ somewhat widely from those given by Dr. URE:—

Parts of sugar.	Parts of water.	Specific gravity.
100 dissolved in	50 give a sirup of	1.345
100 "	60 "	1.322
100 "	70 "	1.297
100 "	80 "	1.281
100 "	90 "	1.266
100 "	100 "	1.257
100 "	120 "	1.222
100 "	140 "	1.200
100 "	160 "	1.187
100 "	180 "	1.176
100 "	200 "	1.170
100 "	250 "	1.147
100 "	350 "	1.111
100 "	450 "	1.089
100 "	550 "	1.074
100 "	650 "	1.063
100 "	750 "	1.055
100 "	945 "	1.045
100 "	1145 "	1.030
100 "	1945 "	1.022
100 "	2445 "	1.018
100 "	2945 "	1.015

The annexed table, constructed by NEIMANN at the normal temperature of 63°, with the same object, is also submitted:—

Sugar.	Water.	Specific gravity.	Sugar.	Water.	Specific gravity.
0 ..	100 ..	1.0000	36 ..	64 ..	1.1582
1 ..	99 ..	1.0035	37 ..	63 ..	1.1631
2 ..	98 ..	1.0070	38 ..	62 ..	1.1681
3 ..	97 ..	1.0106	39 ..	61 ..	1.1731
4 ..	96 ..	1.0143	40 ..	60 ..	1.1781
5 ..	95 ..	1.0179	41 ..	59 ..	1.1832
6 ..	94 ..	1.0215	42 ..	58 ..	1.1883
7 ..	93 ..	1.0254	43 ..	57 ..	1.1935
8 ..	92 ..	1.0291	44 ..	56 ..	1.1989

VOL. II.

PAYEN gives the subjoined empirical formula for the estimation of the amount of sugar in a sirup from the indications of its gravity with BEAUMÉ's areometer, namely—multiply the indicated density by two and deduct a tenth of the product, the remainder will represent the per centage of sugar in the liquor. Thus, if the indication observed be 20, the result will be—

$$20 \times 2 \text{ minus } \frac{20 \times 2}{10} = 36.0 \text{ per cent.}$$

If the sirup be of pure crystallized sugar the product of the density multiplied by two is reduced by one-twelfth; thus—

$$20 \times 2 \text{ minus } \frac{20 \times 2}{12} = 36.67 \text{ per cent.}$$

If, however, a sirup contains other solid bodies besides sugar, it is clear that the specific gravity of the solution alone can give only an imperfect criterion of the quantity of sugar present. Recourse is then had to the power which a solution of cane-sugar has of turning to the right the plane of polarized light. When therefore a liquid contains cane-sugar without any other substance possessing the same optical property, the quantity of sugar may be determined with great exactness by measuring the deviation which the liquid produces in the plane of polarization. To apply this method, the deviation must be known which is produced by a solution of sugar of known strength. For this purpose a given weight, ϵ , of sugar is dissolved in such a quantity of distilled water that the solution occupies a given volume, V . Sufficient of this solution is taken to fill a tube of a certain length, and the deviation suffered by the plane of polarization of the luminous ray passing through this tube is measured. Let this deviation be α . Let then other quantities of sugar be dissolved in sufficient water to give the same volume of solution, V ; and let the deviations produced by these solutions in the same tube be α' , α'' , α''' , *et cetera*; then the quantities of sugar contained in the volume, V , of these liquids will be represented by

the products $\epsilon \frac{\alpha'}{\alpha}$, $\epsilon \frac{\alpha''}{\alpha}$, $\epsilon \frac{\alpha'''}{\alpha}$, *et cetera*, respec-

tively. If the sugar examined, instead of being pure, is mixed with other but inactive substances, it is evident that these same products express the absolute weights of pure sugar contained in the weights of substances employed in the formation of the liquids of the given volume, V . It is possible to employ proof tubes of different lengths; but it is then necessary to reduce by calculation the observed deflections to those which would have been produced in the same tube.

It often happens that solutions of sugar which have to be examined are turbid or strongly colored. When this interferes with the examination, they must be clarified and rendered either quite colorless, or when this is not possible the color must be at least reduced. This may generally be effected by precipitating the coloring matter of the sirups with subacetate of lead; but at a sugar-work the most convenient and complete method is a filter of animal charcoal. The filtrates are then examined optically. When sirups

contain, besides cane-sugar, other constituents which exert an action upon the plane of polarization, the amount of cane-sugar present may be often determined by inverting, by means of hydrochloric acid, the rotary power of the cane-sugar. No other saccharine substance is, in fact, known which suffers a similar change under the same circumstances.

If, for instance, the liquid under examination contains besides cane sugar, glucose, whose rotary action on the plane of polarization is in the same direction as that of cane sugar; if α' be the deviation observed to be produced by the liquid, then α' is evidently the sum of the separate deflections of the cane-sugar, x , and of the glucose, y . About one-tenth of its volume of hydrochloric acid is added to the sirup, and it is kept for ten minutes at a temperature of 140° – 154° . The cane-sugar is thereby completely transformed into noncrystallizable sugar, which turns the plane of polarization to the left, while the rotary power of the glucose undergoes no alteration. When this change has been effected, the new deviation, α'' , of the liquid is observed. It is now the difference between the deviation, y , of the glucose and that of the noncrystallizable sugar derived from the cane sugars. But the degree of dilution of the liquid having been changed by the addition of the hydrochloric acid, the deviation observed, α'' , must be replaced by the deviation, $\frac{10}{9}\alpha''$, which would have

been observed if the inversion could have been produced without the addition of hydrochloric acid. Admitting therefore that a quantity of cane-sugar which effects a deviation, x , gives rise to a quantity of noncrystallizable sugar which effects a deviation, rx , there is—

Before the inversion, $x + y = \alpha'$.

After the inversion, $y + rx = \frac{10}{9}\alpha''$.

From these two equations the quantities x and y may be determined. The coefficient of inversion, r , is determined once for all by a special experiment performed upon pure cane-sugar at the temperature at which the experiments have afterwards to be made. According to BIOT, this coefficient is 0.038 for hydrochloric acid at a temperature of 71.6° .

The process is the same when the cane sugar is mixed with noncrystallizable sugar, turning the plane of polarization to the left. In this case the initial deviation, α' , of the liquid is the difference between the deviation to the right, x , of the cane-sugar, and the deviation, z , to the left of the noncrystallizable sugar. After treating with hydrochloric acid, the deviation, α'' , is composed of the deviations of the original noncrystallizable sugar, and of that produced by the action of the hydrochloric acid. One then has—

Before inversion, $x - z = \alpha'$.

After inversion, $z + rx = \frac{10}{9}\alpha''$.

It is important in examining optically noncrystallizable sugar always to employ the same temperature,

because a change of temperature materially affects the rotary power of this kind of sugar.

E. MAUMENÉ proposes chloride of tin— $\text{SnCl}_2 \cdot 5 \text{HO}$ —as a reagent for sugar. By boiling he obtains a constant result. One part of sugar evaporated with fifteen to thirty parts of chloride of tin, and heated up to 220° or 226° , produces a brown body, insoluble in acids and alkalies. This he calls caramelin. It consists of $\text{C}_{12} \text{H}_{14} \text{O}_4$. Grape-sugar, cellulose, dextrin, and such bodies, give the same compound.

According to HORSLEY, alkaline chromate of potassa produces a green color in solutions of sugar, easily detected in a few drops.

FEHLING analyses sugar metrically in a beautiful way; but it is better suited to minute quantities than to the work of a sugar-house. He has a normal solution, made of—

40 grammes of sulphate of copper,
160 grammes of neutral tartrate of potassa, or 200 grammes of tartrate of soda,
700–800 grammes of caustic soda, specific gravity 1.12.
This is diluted with water to 1154.5 cub. c.

Of this solution 1 cub. c. = 0.0050 grape-sugar, or 0.00475 cane-sugar.

Grains may be used instead of grammes, and then 1 grain = 0.0050 grape-sugar, without change of calculation.

100 parts of grape-sugar, ... }
95 “ cane-sugar, ... } = 220.5 CuO, or 198 Cu₂O.
90 “ starch, }

This mode is peculiarly valuable for urines, as it measures the smallest quantities. The urine should be diluted from ten to twenty times with water. It should be boiled a few seconds after adding each portion of copper solution. The sugar of urine is grape-sugar.

On the Manufacture of Cane-sugar.—The manufacture of sugar from the sugar-cane may be divided into five parts. 1. *The cultivation of the cane.* 2. *The extraction of the juice.* 3. *The purification of the juice.* 4. *Its concentration; and* 5. *its crystallization.*

1. *Cultivation of the Cane.*—The sugar-cane—*Arundo saccharifera*—is an indigenous plant of the gramineous family. Cultivators distinguish three great varieties—the Creole, the Batavian, and the Otaheite cane. The first is indigenous to India; but it has been transplanted to other soils, such as those of Sicily, the Canaries, the Antilles, South America, and the West Indies. It is known by its thin, very knotty stem, and green leaves. The Batavian cane is a native of Java, but is met with at present in some of the sugar plantations of the New World and the West Indies; it is covered with purple stripes, and has a heavy foliage. The Otaheite variety is spread over the West Indies and South America, and is esteemed by far the richer and more productive of the several species. There are besides, the purple-banded and the purple Otaheitian and the ribbon cane. The Bourbon is said to be the same as the Otaheite cane of Singapore.

The sugar cane in a state of maturity is usually from six to fifteen feet in length, and from one and a half to two inches in diameter. It is jointed, and the distance of the joints from one another is from three to seven inches. These joints correspond to the extremities of hexagonal cells of which the intermediate

portions of the stem are composed, and which are in the living state of the plant filled with a solution of sugar. The exterior of the cane is smooth, hard, and cylindrical, and is covered with a coating containing a large quantity of silica. Germination occurs at the joints, and takes place at the opposite sides of alternate joints.

The sugar cane grows from pieces or slips of itself containing germs, and these develop rootlets at the joints, which draw sustenance to the young shoot as it increases. In the course of time the buds in the radicle, or root joints, of the first cane throw out roots, and form a radicle for a second stem; and in this way it happens, under favorable circumstances, that several canes are produced from the parent stock for a period of about six years, sometimes even for twenty years. From the first and second year, however, the canes diminish in the length of joint and circumference, and so the quantity of juice decreases; but it is alleged that the juice is much richer than when younger, and also produces a finer sugar. A common mode of obtaining successive crops is as follows:—When an old cane has been cut for its sugar, the incision is made some inches below the ground and the stump covered with mould. In about twelve months' time the offshoots from the original cane are ready for transplanting. In planting these slips or *ratoons* the system of wide planting is gradually superseding the old close planting. In addition to the advantage which the former kind offers in allowing the use of the horse-hoe for weeding, the great length of the root of the sugar-cane, which often extends laterally to a distance of six, and vertically to a depth of two feet, makes wide planting imperative, when rapidity of growth, as determined by quick absorption, is required. The cane holes are advantageously formed five feet from one another, in rows which are also five feet apart.

Of late years the system of cultivation of the sugar-cane has attracted considerable attention, as well in regard to the preparation of the soil as to the manner of planting. Formerly the custom of preparing the land by manual labor was followed; it is sometimes so still, and the consequence of not having the soil sufficiently disintegrated to the proper depth required by the plant, made itself apparent in the defective harvests of the plantations which followed; besides, by the practice of utilizing for fuel the *magass* or expressed cane, called *cane straw* and *cane trash*, instead of returning it to the land, the latter was rendered deficient in humus, and, therefore, not suited to retain the proper quantity of moisture, which, in the warm climates of its growth the cane absolutely requires for its proper development. And, although the ashes of the refuse might be consigned to the soil, yet this, instead of improving, rather defeated the objects which the cultivators had in view, as by the use of too much mineral matters as a manure, the sugar secreted by the plant was rendered uncrystallizable, and so, in a comparative sense, lost to the planter. An excess of soluble salts should always be guarded against in the cultivation of the sugar plant; but the fertilizer should be rich in humus and nitrogenous constituents, as the consumption of both these classes of bodies by the plant is greater in a much larger proportion than of mineral

fertilizing matters. The knowledge of these facts has led to the desire of employing such matters as blood, decomposed flesh, rotten fish, wool refuse, and the like, for manure in the sugar plantations. Charred peat would, in the opinion of the Editor, be a valuable adjunct to such matters, as it would materially prevent evaporation of the natural moisture of the soil, and supply carbon to the growing plant. Another feature in the modern innovations on the old system of culture is, that the *ratoons* or *stocks* are planted much wider apart. Various parties differ in their views in this respect—some recommending the plants to be set four feet apart in rows six feet asunder; others recommend a greater distance between the rows, such as eight feet; while some state that this should be increased to ten, or that each *stock* ought to have a space allotted to it of six and eight feet either way from the next one. It is to be hoped that from considerations like these, of the necessity of pursuing a more rational course of tillage, the planter may, and he doubtless will, be led, in the course of a few years' practice, to adopt the mode which enlightened observation and study will show to be most advantageous.

The frequent droughts which occur in the countries adapted to the cultivation of the sugar plant, render the artificial prevention of the too rapid evaporation of the water, which would be very injurious to the freshly-planted ratoons, of the highest importance. The great bulk and solidity, and the richness in mineral constituents of the stem of the sugar-cane, would cause a rapid impoverishment of the soil, were not some adequate return made to it. Both purposes are effected by surrounding the stems of the newly-planted ratoons with the *megass* or cane from which the sugar has been extracted.

Canes require a well drained but still a rich and moist soil. Land with much saline matter is frequently found to prevent the canes ripening; they remain green and watery.

One variety greatly in cultivation in Jamaica came from Otaheite. When this cane is well cultivated, and in favorable soil, it rises in the first year to twelve or fourteen feet in height, being six inches in circumference, and having joints six inches apart. No field, however, will give an average so high as this. Plants such as these will produce two and a half to three tons of dry sugar per acre, but the average is considered good at two tons per acre. It sometimes attains maturity in ten months. Its foliage is of a pale green; leaves broad and much drooping, and flowering or arrowing in a manner graceful and ornamental. It requires a rich soil. The *yellow violet* may be put in poorer soil. It gives a fine sugar, but not so much as the Tahiti cane. It has a dark-green foliage. The juices of the two are frequently mixed. The *purple violet* is from Java, and is eight to ten feet high, and six inches in circumference. On the joints of the cane there is a large amount of a resinous film, which sometimes completely shades the purple beneath. This resin is very hard and troublesome to grind. The sugar of this cane is excellent. The cane itself is hardy, and is sometimes used in Jamaica as a border to other canes, defending them against the trespassing of cattle.

The large red cane of Assam is said to flower in eight months, and to give similar sugar to the Tahiti cane. In Bengal a large red cane is cultivated which gives excellent sugar. The China cane is said to be extremely hardy, standing both cold and drought, and, with abundant rain, giving out as many as thirty shoots. It resists the inroads of the white ants, which cannot penetrate its hard crust, whilst it is also safe against the teeth of the jackals. It requires, however, a stronger mill for grinding than the other varieties mentioned. Mr. WRAY asserts that the Salangore cane is the finest in the Straits of Singapore, and perhaps in the world. He says that he has cut five from one stool, which were of a weight of from seventeen to twenty-five pounds. They have been known to produce seven thousand two hundred pounds of undrained sugar per acre, equal to five thousand eight hundred of dry sugar for shipping.

Dr. LIVINGSTONE says that sugar is cultivated in the Shire valley, as well as many parts of Africa near the Zambesi, and may be had for as little as one half-penny per pound. There is field enough for great enterprise in that direction. The amount obtainable has not been investigated.

The time of harvesting the cane varies with the mildness of the season, the locality, the nature of the soil, and the variety of the cane cultivated. Generally a dry, smooth, brittle skin, a heavy cane, a grey pith,

approaching to brown, and a sweet glutinous juice, indicate the maturity of the cane. A dry season is the time in which the canes should be cut, if possible, so that, by the absorption of too much moisture, the juice may not be diluted, and thus occasion increased trouble and expense in preparing the sugar from it. The canes are cut as close to the *stole* or root as possible, as well because the lower joints are found richer in sugar, as to give vigor to the ratoons, which are to spring from the old stock; the tops, with one or two joints, if they be not sufficiently ripe, are cut off, and the canes tied in bundles, and conveyed to the crushing mill. It is absolutely necessary that the cane be cut just before expressed in the mills; for, if allowed to remain any length of time at the high temperature of the climate, the sugar ferments, and a considerable loss is consequently occasioned.

Dr. EVANS gives the products of an acre of canes in Barbadoes as—

Weight of canes.	Weight of juice.	Extract.	Extract per 100 pounds of juice.	Extract per 100 pounds of canes.
30 tons. . .	60,480 lbs. . .	10,886 lbs. . .	18·0	16·20
30 tons. . .	47,040 lbs. . .	8467 lbs. . .	18·0	12·6
30 tons. . .	33,600 lbs. . .	3500 lbs. . .	10·0	5·0
30 tons. . .	33,600 lbs. . .	7280 lbs. . .	21·6	10·8

An acre may be said to yield thirty tons of canes. The following table gives the produce in juice and sugar:—

Juice obtained per cent.	Juice in pounds.	Pounds of Sugar.			Subtract for Molasses and Skimmings, at 12 per cent.			Pounds of dry Sugar yielded by one Acre,		
		At 18 per cent.	At 20 per cent.	At 22 per cent.	At 18 per cent.	At 20 per cent.	At 22 per cent.	At 18 per cent.	At 20 per cent.	At 22 per cent.
70	47,040	8,468	9,408	10,348	705	792	862	7,763	8,616	9,486
75	50,400	9,092	10,080	11,088	757	840	924	8,335	9,240	10,164
80	53,760	9,676	10,752	11,827	806	896	994	8,871	9,856	11,173

This supposes the juice to stand at 10° Beaumé; at the same time all the numbers given are above the amount actually obtained in practice, which does not appear to be above five thousand pounds per acre.

But it is difficult to tell the real amount of sugar obtained on the estates. The books on the subject are frequently very one-sided, or very confused, or they are not possessed of the information except for certain estates. Perhaps four thousand pounds of sugar and one hundred and seventy gallons of rum, twenty per cent. over proof, is a very fair specimen of the yield.

The following table by M. DUPREZ is given by Dr. EVANS. The average amount of juice from one hundred pounds of canes was—

1. By mills having horizontal rollers—motive power not stated—probably steam	61·2
2. By mills, motive power steam	60·9
3. By mills, motive power wind and steam	59·3
4. By mills having vertical rollers	59·2
5. By mills, motive power cattle	58·5
6. By mills, motive power wind	56·4

but 70 can now be obtained by greater power, and some speak of 80.

Of the eighteen to twenty-two per cent. of sugar in the cane, it is generally believed that no more than eight is obtained crystallized.

If only fifty per cent. of the juice is taken from the plant, and thirty still remain in it, three-eighths of the sugar are taken away in the megass and burnt

as fuel. Sugar must be to the planter at least worth twenty pounds per ton, whereas he could get coals from England at one pound. But this would not be an important loss, it is said, if the ashes of the megass were only taken and thrown on the soil, as was shown by Dr. STENHOUSE. The climates which grow sugar grow ligneous fibre rapidly, and it is well to use it for fuel when it can be obtained. The ground, however, must not be deprived of its inorganic constituents. It is also important to use the megass early, as the sugary matters unavoidably left in it oxidize, and, of course, give less heat in burning. It is well, however, to burn as little sugar as possible, at the same time to avoid an excess of soluble salts.

The following tables are from PAYEN:—

OTAHEITE CANE AT MATURITY.

	Centesimally.
Water,	71·04
Sugar,	18·00
Cellulose, ligneous matter, pectin, and pectic acid,	9·56
Albumen and three other nitrogenous matters,	0·55
Cerosin, green matter, yellow coloring substance, substance capable of being dyed brown, and carmine, fatty matter, resins, essential oil, aromatic matter, and a deliquescent substance,	0·37
Insoluble salts 0·12; soluble 0·16; consisting of phosphates of lime and magnesia, alumina, sulphate and oxalate of lime, acetates, malate of lime, potassa, and soda, alkaline chlorides, and sulphates,	0·28
Silica,	0·20

100·00

CANE ONLY AT A THIRD OF ITS DEVELOPMENT.

	Centesimally.
Water.....	79.70
Sugar.....	9.06
Cellulose and incrustated ligneous matter,	7.03
Albumen and three other nitrogenous substances, ...	1.17
Starch, cerosin, green matter, yellow coloring substance, and bodies colorable to brown and carmine, }	1.09
Fatty, aromatic, and hygroscopic substances, essential oil, soluble and insoluble salts, alumina, and silica,	1.95
	100.00

The fresh cane has been estimated to contain—

	Tahiti. Per cent.	Cuba. Per cent.
Water	72.1	65.9
Ligneous fibre.....	9.9	16.4
Sugar and other substances	18.0	17.7
	100.0	100.0

The juice of Martinique cane has been found to contain—

Sugar	20.9
Water	77.2
Organic substances not sugar	0.2
Inorganic salts	1.7
	100.0

The megass or residue, after passing the rollers—

Sugar	7.9	7.3
Molasses	3.0	2.7
Ligneous matter and earthy salts	38.6	39.5
Water	50.5	50.5
	100.0	100.0

CASASECA has analyzed the Havana cane—the *creole*—and found—

	Cane entire.	Cane peeled.	The rind.
Water	77.0	77.8	69.5
Sugar and soluble substances	12.0	16.2	11.5
Ligneous matter.....	11.0	6.0	19.0

He says that 23 of dry cane contain 12 of sugar, and 23 of the dry rind only 8.6.

	Cane sugar.	Grape sugar.	Water.	Ashes.	Water of the insoluble part.	Remainder—caramel, gum, and acids.
Ten sorts of Java	98.6 — 83.1	5.5 — 0.3	6.1 — 0.3	1.9 — 0.2	0.2 — 0.0	3.5 — 0.5

White sugar	99.7	0.2	0.1	—	—	—

Twelve kilogrammes of molasses of cane sugar contain according to PAYEN—

Sugar	7.561.00
Acetate of potassa	0.209.30
Chloride of potassium	0.114.60
Sulphate of potassa	0.085.50
Mucilaginous matter	0.076.30
Phosphate of lime	0.052.00
Nitrogenous substances.....	0.050.00
Silica	0.023.90
Acetate of lime	0.016.20
Phosphate of copper	0.000.20
Water	1.800.00
Glucose and uncrystallizable sugar	1.561.00

RICHARDSON found sugar and the molasses from it to contain—

	Sugar.	Molasses.
Potassa	19.42	36.23
Lime	14.67	12.72
Magnesia	10.72	11.14
Oxide of iron	6.55	2.62
Oxide of copper	0.71	trace of
Protoxide of manganese	trace	both

The amount of water in the sugar-cane increases according to CASASECA, towards the top; the greatest amount of sugar is found in the lower third of the cane, but much less in the upper part; the centre third contains about an average of the whole. The water even of the joints increases on rising.

The pure or nearly pure juice, when the green matter is removed, contains—

	Per cent.
Water	81.00
Sugar	18.20
Organic matter, precipitated by lead salts	0.45
Saline matter	0.35
	100.00

Cane juice has a specific gravity of 1070 to 1090—10° to 13° Beaumé. It has been obtained as low as 1046, and as high as 1110, at 80° Fahr. It is opaque, frothy, and of a yellowish green. The green part may be filtered out, leaving a pale yellow fluid, which is almost pure sirup. The green scum consists of chlorophyll, cellulose, ligneous fibre, and albumen. Its analysis given by AVEQUIN is—

	Per cent.
Cerosie—a peculiar wax.....	50.0
Green matter	10.0
Albumen and ligneous fibre	22.7
Phosphate of lime	3.3
Silica	14.0
	100.0

A gallon of juice, weighing about ten and three-quarter pounds, contains about twenty-seven grains of this greenish scum.

MULDER believes that the light-colored sugars contain most cane-sugar generally. He also says that the many varieties into which sugars are divided in Holland are not well based.

MULDER gives the following analyses of several raw sugars:—

	Water.	Ashes.	Water of the insoluble part.	Remainder—caramel, gum, and acids.

Four kinds of common sugar	0.121	—0.225

It is found that sugar which is brought over in iron vessels, frequently oozes out and attacks the iron, doing injury to the vessel. Iron is rapidly dissolved by sugar. The sugar may become a little acid and then attack the iron, but it soon throws it down again as an oxide, as Dr. GLADSTONE has observed, and thus a small amount of sugar destroys a large amount of iron. Dr. GLADSTONE obtained the following compound:—

	Found.	Calculated.
Protoxide of iron	17.20	17.39
Sugar	82.80	82.61

Sugar readily decomposes a sesquioxide of iron in solution into a protoxide. Dr. GLADSTONE did not find that zinc prevented the oxidation of the iron. Zinc itself is not easily separated from sugar. Copper is scarcely acted on by sugar, but the oxide is dissolved, and lead is dissolved in no small quantities. This corroding power is not known to belong to pure crystallizable sugar, and the experiments of the above chemist must be taken as referring to the molasses, *et cetera*, united with it.

From the analyses on page 972 may be learned the absolute necessity of permitting the cane to attain its full growth and maturity before being cut for the extraction of its secreted sugar; and further, that in the system of manufacture in some cases adopted, the exhaustion of the cane is so imperfect as to leave fully one-half or three-eighths of its juice in the straw; thus, at the very first outset, causing a loss to the planter or sugar-maker of about one-half the quantity which the cane contains. When the other defects of the manufacture are considered as tending to convert the crystallizable into uncrystallizable sugar, producing fermentation and

water, were found by Mr. THORNTON J. HERAPATH to contain 13.574 parts of ashes, composed of—

	Per cent.
Water	48.940
Organic matter	37.486
Carbonate of potassa	0.146
Sulphate of soda	0.155
Chlorides of sodium and potassium	0.237
Carbonate of lime and some carbonate of magnesia	3.964
Sulphate of lime	1.231
Phosphate of lime and some phosphate of magnesia	2.679
Phosphate of iron and alumina	1.320
Silicious residue insoluble in acids	3.842
	100.000

The dry substance contained 5.42 per cent. of nitrogen.
Undried

The prepared sugar is very pure. MULDER found in one hundred parts of dry sugars—

	Ashes.	Grape-sugar.

oxidation, the clue to the enormous waste in the manufacture of sugar is at once obtained. These losses may be grossly set down as being due—

To imperfect extraction of the juice 45 to 50 per cent.
To transformation to uncrystallizable sugar, *et cetera* } 12.5 to 15 "

Loss of crystallized sugar 57.5 to 65 "
Balance, or quantity of sugar obtained 42.5 to 35 "

2. *Extraction of the Juice.*—The sugar exists in the cells of the cane in the state of solution, which constitutes the juice or sap of the plant. Analyses have shown that the quantity of juice and its richness in sucrose, are variable to some extent; but on an average the per-centage of sugar amounts to seventeen or eighteen parts in good cane. The following additional analyses indicate an average composition—

	Centesimally.		
	From Martinique, by Peligot.	From Guadeloupe, by Dupuy.	From Cuba, by Casaseca.
Water	72.1	72.0	65.9
Sugar	18.0	17.8	17.7
Ligneous matter	9.9	9.8	16.4
Salts	—	0.4	—
	100.0	100.0	100.0

Such also is the average composition of the cane of the third, fourth, and succeeding years' growth from the parent stock, as shown by PELIGOT's researches on this subject. HERVEY examined two specimens of sugar-cane of Guadeloupe, and the megass which they yielded. The samples were grown on two different soils—No. 1 being produced by a dry, calcareous, and elevated one; and No. 2, by a low soil in the neighborhood of volcanic eruptions. The following are his results calculated without water:—

	No. 1.		No. 2.		
	Sugar-cane.	Megass or Straw.	Cane Sugar,	Megass or Straw.	The same brown and decomposed.

The saccharine liquid is extracted from the cane by pressure. The sugar-mills employed for this purpose are chiefly three, namely, the horizontal and the vertical roller mill, and the hydraulic press. The latter,

however, has not received general adoption. The accompanying woodcut—Fig. 554—shows the construction of horizontal sugar mill.

The vertical mill, in which the crushing cylinders

Fig. 554.

are placed vertically, has the advantage of being more easily cleaned; but it is less easily fed, and is more costly in its construction. A great deal depends upon the right adjustment of the distances of the three rollers, a too near approximation causes, on the one hand, an increased expenditure of force in the working of the mill, and on the other, a too great distance allows a portion of the juice to escape extraction, and to be carried off in the megass. The distance between the feeding roller and the upper one is about half an inch; the delivering roller is still closer to the upper one. In feeding a horizontal mill, the canes are cut into lengths of about three feet, and so spread upon the feeding board that these may overlap one another as little as possible. Mills have also been constructed with five and with four rollers. When five rollers are employed three are placed below and two above. A five-roller mill is said to extract ten per cent. more juice from the cane than a three-roller one; but the megass is thereby much broken, and a much greater expenditure of mechanical power is required to work the mill. In the four-roller mill, where two rollers are placed below and two above, while a greatly superior amount of juice is obtained, the expenditure of force is said to be not much greater than in the ordinary three-roller mill; hence it is probable that the four-roller mill will gradually supersede those now generally in use.

Some years ago a method was patented by Mr. MICHIEL for extracting the sugar from cane without the use of the mill; it was proposed to cut the canes into thin slices and treat them with lime water. The object of this was to render the nitrogenous constituents of the

cane insoluble. On treating the so-prepared canes with water, a sirup is obtained of a purity much greater than that obtained directly by mechanical means. Probably the mechanical difficulty experienced in slicing the canes has prevented the adoption of this method. The following are the experiences of Dr. EVANS—given in the *Sugar Planter's Manual*, published in 1857—in regard to the advantageous working of a sugar mill:—1. The rollers should be approximated as closely as the work which they have to perform will admit of. In mills in which the rollers observe a vertical direction, the space between the first and second should scarcely, if at all, exceed a quarter of an inch, whilst a distance of one-sixth of an inch is the most that should be allowed between the second and third. When they are placed horizontally, the upper one should be distant a space of one-fifth to a quarter of an inch from the two lower. 2. The velocity of the rollers should be rendered as uniform as possible, not by diminishing the amount of the motive power, but by a carefully regulated supply of canes. 3, 4. The megass should be invariably repassed between the rollers so as to extract as much as possible the juice which still remains in it. When canes are rich, and their juice of considerable density, the megass should be sprinkled with a little water, or, where it is practicable, exposed to the action of steam before it is submitted to the pressure; but when the canes are large, green, and watery, this may be dispensed with.

The amount of juice obtained from the cane is not always a criterion of the comparative yield in sugar. The drought or humidity of the season preceding the cutting of the canes determines the presence of a less

or greater amount of water in the cane, while the quantity of sugar remains for a time unaffected. Between moist and dry seasons, and thorough and imperfect crushing, the yield of juice may vary from fifty to seventy-five per cent. of the weight of the canes employed.

The following table shows the proportions of the solid constituents—other than sugar—in cane juice. The relation of these amongst one another is probably pretty constant, although the quantity of sugar and of water may vary much with the age of the plant and the season at which the juice is extracted.—

Ure.

One hundred parts of solid constituents contain—

Sulphate of potassa,	11.3
Phosphate of soda,	10.2
Chloride of potassium,	5.3
Acetate of potassa,	40.6
Acetate of lime,	22.9
Silicic acid,	9.7

100.0

The methods employed in Hindostan and Ceylon for the extraction of the sirup or *goor* from the cad-goollee and other species of indigenous cane are so imperfect as to require no special description.

Captain MARGETSON, R.N., has proposed to cut the cane in pieces, and dry it as beet-root is dried, sending the substance home for the extraction of the sugar. This is a very promising field of inquiry.

3. *The Purification of the Sirup.*—The removal of impurities from the juice, as it is delivered from the mill, may be divided into two processes, defecation and clarification.

The crude cane juice contains, besides sugar and water, the impurities—earthy insoluble particles, fragments of the crushed cane or megass, albumen, caseine, wax, soluble coloring matter, and soluble salts. The coarser of the insoluble particles are sometimes removed mechanically previous to the process of defecation. But certain of the nitrogenous impurities of the crude juice if left in contact with the sirup speedily determine its fermentation, thereby occasioning loss in sugar, and owing to the subsequent conversion of the alcohol generated by fermentation into acetic acid, causing the corrosion of the metallic portions of the machinery, and the introduction of metallic acetates into the sugar. It is of the greatest importance that the process of defecation, whereby the nitrogenized compounds are removed, should follow with as little delay as possible upon the extraction of the juice. For this reason the storing of the sirup in tanks until a sufficient quantity is obtained for purification, is to be reprehended. The first filtration also should, for the same reason, be performed as rapidly as possible. This filtration is effected through a double sieve, the metallic meshes of the first sieve being about one-twelfth, those of the lower about one-thirtieth of an inch asunder. The sirup is run from these sieves, or directly from the crushing mill, through a wooden gutter lined with lead to the clarifiers. These are a series of copper cauldrons capable of holding from three thousand to four thousand gallons each. The bottoms of the clarifiers are usually concave, being bulged inwards from below.

Each cauldron is provided with a separate fire, the flues from which run into a common chimney, and each fire is provided with a separate damper for regulating or stopping the draught.

Defecation.—When this is performed in the Colonies, the sugar is boiled down from the strength of 10° Beaumé only to about 27° or 28°, which is the strength suited for hot filtration. When it is performed in England, the sugar is dissolved in water, so as to be of the strength of 27° Beaumé.

Lime is the agent most frequently employed in defecating the sirup; but considerable differences of opinion exist concerning the best method of its application. The lime should be thoroughly burned and quickly slaked with hot water, enough water being added to give the consistence of a cream. This should be then filtered through a fine wire sieve in order to remove silicious particles and fragments of unslaked lime or unburned limestone. Some sugar manufacturers adopt the following process:—When the sirup in the clarifiers has attained the temperature of 130° Fahr. successive portions of the cream of lime are added, until the acids in the sirup—acetic and lactic—have been completely and exactly neutralized, which is shown by its neutrality to blue and red litmus paper. The mixture of sirup and lime is thoroughly incorporated with an oar, and the whole left to digest for about a minute. The portions of cream of lime successively added to effect neutrality should not contain more than about four ounces of solid lime per gallon. The product so obtained is run off through a stop-cock in the clarifier, either through bag filters or through charcoal filters, subsequently to be described. In the more common process of defecation, however, after neutralization by cream of lime, as above described, the heat is urged until a temperature just below the boiling point of the sirup is reached. A thick scum is then formed upon the surface of the sirup, and the clarification is judged complete when this scum breaks and a white froth appears in its interstices. In all cases an excess of lime is to be avoided, partly because nitrogenous matter, upon the removal of which, from an acid solution by heat and lime, the clarification in a great measure depends, is redissolved by an excess of this agent, but mainly because of the destructive action of caustic earths on sugar. If, however, an excess of lime has been added, it may be remedied by the addition of small quantities of a solution of alum. When this salt is added to any alkaline solution with excess of lime, its alumina is precipitated and rises with the same, fixing a portion of the coloring matter of the sirup at the same time, and thus assisting in the clarification. Of the simultaneous products found in this reaction, *videlicet*, sulphate of lime and sulphate of potassa, the first is in a great measure insoluble and rises with the scum; the second, however, is soluble in the sirup, and cannot be subsequently separated from it; and this is the only drawback in the employment of alum to neutralize overlimed sirup. Sulphate of alumina, however, is not subject to this disadvantage, and may, therefore, advantageously replace alum in the neutralization of overlimed sirup.

Other substances have been employed for the defe-

cation of cane juice, of which the principal are bullock's blood, nut-galls, sulphate of zinc, alum, sulphate of alumina, sulphuric acid and lime, and subacetate of lead. As bullock's blood is almost exclusively employed in the defecation of beet-root sugar, its application will be described under that head.

Nut-galls.—After the clarification by means of cream of lime of four hundred gallons of sirup has been effected, the temperature is raised to 150° or 160°, and a decoction of nut-galls is added, formed by digesting two ounces of the bruised galls in half a gallon of boiling water. The mixture is stirred for two or three minutes with an oar, boiled and strained through bag filters.

Sulphate of Zinc.—Twelve ounces of sulphate of zinc are added to a clarifier of three hundred gallons. The sirup is then neutralized with cream of lime, boiled and filtered.

This process has not been used, as it is difficult to remove the taste of the zinc.

Alum.—Four pounds of alum in solution are added to a clarifier of three hundred and fifty gallons; as it begins to get warm the heat is rapidly raised to 140°, and the sirup neutralized with cream of lime.

Alum should never be used, as it introduces salts of the alkalies, which cannot be removed.

Sulphate of Alumina.—A pound of sulphate of alumina is added to every hundred gallons of juice, and the whole quickly neutralized with lime and filtered as before; still not of much value.

Ammonia has been proposed as an addition to sugar, especially to beet-root juice; but its value has not been shown.

Alumina and Sulphate of Lime.—The alumina obtained from two pounds of alum by precipitation along with sulphate of lime, by means of carbonate of lime in suspension, is washed by decantation and added to one hundred gallons of cane juice. When the temperature of the sirup has reached 150°, lime is added to neutralization and the juice is then filtered.

Sulphuric acid diluted with thirty times its volume of water is added to the sirup—for three hundred gallons of the latter, two fluid ounces of sulphuric acid are employed—at a temperature of 120°; four ounces of lime are then added, and when the temperature reaches 170°, the sirup is neutralized with more lime and filtered.

The value of this method is extremely small.

Subacetate of Lead.—It has been proposed to effect the defecation of the sirup by the successive employment of subacetate of lead and phosphate of lime. Subacetate of lead has the power of throwing down the whole of the coloring matter and other organic foreign substances present in the sirup. But the subsequent separation of the lead which is in solution by phosphate of lime, is either not perfect in the presence of sugar, or requires more delicate manipulation and greater care than can be usually looked for in sugar manufactories. The deleterious action of repeated though very minute doses of lead on the system has prevented its employment as a defecating agent.

Dr. SCOFFERN precipitates the lead by sulphurous acid, and by this means it is found that he can remove

it all; but the dangers attending the use of lead are so great, that his process, although beautiful when done well, and perfectly capable of being done well, has been discouraged if not prohibited, and the plan will therefore probably be abandoned. Man's constant accuracy cannot be trusted. *Tin* has been tried, but is not practically found useful.

When the scum has risen to the surface, and the clear sirup is seen through its cracks, the approach of which point is usually judged of empirically by the thickness of a portion of the sirup removed from the clarifier, and by the equalization in size of the bubbles formed in the liquid, the defecation is complete. The defecated sirup is then removed from the scum by tapping, or the latter is removed from the sirup by skimming, in both cases sufficient time being allowed for the heavier portions of the scum to subside. As the scum always contains a considerable portion of sirup in its pores, it is generally submitted to pressure in a simple lever press, and the extract added to the liquid which has been tapped off. Fig. 555 shows the usual form of the clarifier.

In those countries where fuel is cheap, and especially in those manufactories where steam is employed, either as a motive power for the mill, or the vacuum pan—afterwards to be described—or for other purposes,

Fig. 555.

the heating of the clarifier is sometimes effected by means of steam. It is clear that as the temperature requisite for boiling in the open air is above that of boiling water, the steam by which it is effected must be either overheated or high pressure steam. And as in most sugar growing lands fuel is scarce, and as a great use of fuel attends the application of overheated steam, high-pressure steam is employed. This is usually conveyed by a copper worm through the clarifier, the steam passes downwards round the spirals of the worm, and the condensed water is discharged under pressure.

Simple Filtration.—The process of defecation always leaves impurities in the sugar, either in the form of suspended scum, or when filtration is not performed previous to the defecation of the mechanical impurities formerly mentioned. In all cases it has now to undergo another filtration.

It is usual to run off the sirup at once from the clarifiers upon the filters, and the preceding diagram shows the simplest arrangement for this purpose. The matter of the filter is always cotton. Woollen textures are rapidly destroyed by the alkaline nature of the scum. The forms given to the filters are chiefly two—the leaf-filter of *LOVERING* and the bag-filter of *TAYLOR*.

The leaf-filter is composed of a series of cotton bags stretched over thin quadrangular frames, which keep the sides of the bags apart, and cause them to present a smooth even surface instead of folds, thus greatly facilitating the operation of cleaning, when it has to be performed. These frames are arranged side by side in a box, and the juice which filters from without inwards, escapes by a hole in the bottom of the frame. The juice is poured into the box outside of the frames, and the filter, therefore, is not clogged by impurities as readily as *TAYLOR*'s filter, in consequence of which it works more rapidly and does not require to be cleaned so often.—*M^cCulloch*.

TAYLOR's bag-filter—Fig. 556—consists of a number of cotton bags about two feet in length and a foot in diameter when fully extended. Into their narrow mouths the nozzles of the tubes pass which deliver the sirup. The bags are fastened on the nozzles by means of a sliding ring. Each bag is inclosed in a cylindrical one of canvass about four inches in diameter, the object of which is to prevent the swelling out of the interior cotton filter. In such a filter of course the interior bag is much folded; nor can it in this state present the same amount of filtering surface as it would were it fully inflated. It may indeed be questioned whether

Fig. 556.

with tolerably clean sirup such a folded filter offers much advantage above a filter of the size and shape of the exterior canvass bag.

When the leaf or bag filter has become choked it

must be washed; this is sometimes done by machinery. The use of very dilute hydrochloric acid or of acetic acid facilitates the washing, by dissolving the lime in the scum. But the first acid at least, however dilute, weakens the cotton fabric when often applied, and the presence of every acid should, when possible, be avoided in every process of sugar manufacture; because the vinous fermentation to which all saccharine liquids are liable is found to be facilitated by the presence of any acid.

Charcoal Filtration.—The previously described processes of filtration and defecation effect the removal of the mechanical impurities in the sirup, as well as those albuminous and nitrogenous substances which are solidified by the heat of the clarifiers, and removed in the scum which is formed in them. But besides such impurities, the juice of the sugar cane contains various coloring matters whose chemical nature has not been examined, and which are not removed either by filtration or defecation—except where, in the latter process, subacetate of lead is employed. As these coloring matters do not separate by the further evaporation of the sirup, but obstinately remain with it, a further process of decolorization is necessary before the final evaporation is effected. Animal charcoal is the agent employed for this purpose. When the bones of animals are subjected to dry destructive distillation, without access of air, the residue consists chiefly of carbon, and the phosphates and carbonates of lime, with a little of the same salts of magnesia. Such charcoal possesses pre-eminently the power of removing many organic substances from solution when brought into prolonged contact with the liquids which contain them. Thus strychnine when in solution is removed by agitation with animal charcoal. The decolorization of sugar depends upon the same power of animal charcoal. Animal charcoal or bone-black, in removing coloring matter from sirup, undergoes no profound change. It appears to act by a species of superficial affinity; that is, as far as the process can be followed, an affinity that pervades the surface of every one of the minute pores of the charcoal, rendering the actual superficies enormous. But although the charcoal thus remains unchanged, its decolorizing power is so far limited, as when its surface becomes too thickly covered by the coloring matter it withdraws, a charcoal surface is no longer presented to the liquid.

The bone-black preferred by sugar manufacturers for the decolorization of sirup is that obtained from the larger bones of animals—as the thigh and shoulder bones of oxen. This variety is generally not only more compact than that obtained from the smaller bones, or from the bones of smaller animals, but appears to possess a specifically greater decolorizing power. Such bones after burning are reduced to a coarse powder. The grains of which are about the size of small peas. In some manufactories, however, where the process of defecation and decolorization are united, and where powdered bone-black is added to the sirup in the clarifier, the bone-black is employed in a finer state of division, the grains being then of the size of those of the finest gunpowder. But as in this method the bone-black

employed is thrown up with the scum in the clarifier, mixed with the salts of lime and other feculences from which it cannot be separated, it is lost, and consequently the application of bone-black in the clarifier is seldom adopted. The decolorization by filtration through bone-black is generally effected immediately after the filtration through the cotton filters above described. The following description of the two kinds of bone-black filters most frequently employed abroad, but now scarcely used here, is from R. S. M'CULLOCH's report.

Dumont's filter consists of a wooden box of the form of a four-sided truncated pyramid with a double bottom. The inner bottom is a metallic plate pierced with numerous holes; upon it a cotton cloth is laid, and coarse-grained animal charcoal moistened with water is then spread layer by layer; each layer being rendered of uniform thickness, and packed or pressed closely together by means of a sort of trowel. When the bone-black has been thus formed into a compact bed or stratum of about fifteen or eighteen inches in thickness, and within five to ten inches from the top of the box, it is covered with another cotton cloth, and with another metallic plate pierced with holes. The object of the second cloth and metallic cover is to collect any substances which would otherwise obstruct the interstices of the superior stratum of the bone-black—an inconvenient accident which is easily prevented by the use of such a cover, and this cover is readily exchanged for another, should it become itself obstructed. The superior cover is only of use when the previously described filtration through the cotton bag or leaf filter is omitted.

It is important, in order to avoid false passages, that the juice should be constantly at the same level of about three or four inches above the cover of the bone-black. This is accomplished by means of a self-regulating cock.

To facilitate the action of DUMONT's filter—Fig. 557

Fig. 557.

—the bone-black must be perfectly free from fine powder, which would obstruct the passage of the sirup, and thus retard its flow. To render it so it should be carefully sifted each time after revivification.

PEYRON's filter is another form of metallic filter

to be used like that of DUMONT's with coarse bone-black. It is intended, however, to act continuously and without renewal of the bone-black. This filter is cylindrical, in height eight feet, and in diameter thirty-nine inches. The top is closed with a perfectly air-tight cover, and the vacant space of the double bottom communicates by a tube and cock with the top of a second and smaller filter, so that the sirup which has filtered through the first passes through the second, from which, in like manner, it proceeds through a third. The closed top permits the use of hydrostatic pressure to increase the rapidity of filtration, and the juice enters the first filter for that purpose by a tube from a reservoir above. The double bottom of each filter of the series is also provided with another outlet and stop-cock to permit the fluid contents to be drawn off at any time, if desired.

The filters of PEYRON, like those of DUMONT, are charged with coarse bone-black, carefully compressed in layers; after which the fine powder is washed out thoroughly with water, and when this flows perfectly clear the sirup is allowed to pass into the filter, and to remove the water by *displacement*. As soon as the water which escapes from the double bottom is sweet to the taste, it is collected in the reservoir to be evaporated. After the sirup ceases to flow freely, hot water is used to displace that portion absorbed by the bone-black; and as soon as the density of the escaping liquid becomes feeble it is no longer collected. The hot water is then allowed to flow through the filters until they are washed perfectly. Fermentation soon commences in the filter by reason of the dilute sirup and nitrogenous impurities absorbed by the bone-black; and after twenty-four hours, when the fermentation is considered complete, and the impurities taken up by the bone-black are thereby destroyed, the filter is cleaned to prepare it for work a second time, by first passing through it for half an hour a jet of high-pressure steam, and subsequently washing it thoroughly with hot water.

Another form of filter somewhat similar to PEYRON's is as follows:—A series of four cylindrical boxes, provided with perforated false metallic bottoms are connected together as before with stop-cocks in such a manner that each may be removed without disturbance of the rest. If they are all charged with fresh bone-black, and the sirup is run through until it begins to become colored, it follows that the charcoal in the upper boxes must have lost its decolorizing power to a greater extent than that in the lower ones. The highest box is therefore removed; the next highest becomes now the highest, the third becomes the second, and so on—a box of fresh charcoal being introduced below. In this manner the filtration may be carried on with but little interruption for any length of time. To insure the uniform distribution of the sirup upon the upper layer of the box, a mechanical contrivance is sometimes employed. This is of the form of a horizontal tube, perforated with holes throughout its length, but closed

at its ends, and capable of revolving with facility about its centre. The passage of the sirup through the tube and through its orifices determines the revolution of the tube about its axis, and the consequent distribution of the sirup upon its surface.

The filters on the Continent are still frequently of this kind, but such are seldom used in England, where it has been found economical to use them of enormous size, being about thirty feet in height, and four to eight feet in diameter. A filter like this contains about twelve tons of animal charcoal. Charcoal is expected to purify, on an average, an equal weight of fine, or twice its weight of *seconds* sugar.

The same bone-black may be employed any number of times, provided the substances which it has withdrawn from the sirup be removed. This is sometimes done by allowing them to ferment, as in PEYRON's filter; but more frequently by simple rekilning. The kiln made by G. F. CHANTRELL of Liverpool for the revivification of the bone-black is seen in Fig. 558. Those of PONTIFEX and WOOD and others are under the article *Charcoal*.

Perhaps no part of a sugar refinery is more important than the burning of the charcoal or bone-black. This is generally used in small pieces, the largest about the size of a half pea, and slightly elongated in the direction of the length of the bone from which they are formed. It was at one time usual to grind the charcoal to dust, but this habit is now almost entirely given up. When fine the sugar does not run so rapidly through the filter, and it is not mixed with so much facility or so much convenience; besides, it is not so easily burnt or revivified. In general, too, refiners object to the very fine charcoal, and either drive it off by blowers when the charcoal is dry, or remove it by lixiviation. It is sold to the manufacturers of superphosphate of lime at about five to six pounds per ton.

By means of flues a series of brick walls about eight feet in height are heated red hot. The walls are in pairs, each two of which are about eight inches apart. The space between each pair of walls is completely filled with the spent bone-black, the pile of which rests upon the ground. The upper end of each vertical layer forms a part of the heap of spent bone-black, which therefore covers the top of all the walls. When the walls have reached a red heat, and remained for a quarter of an hour at that temperature, enough bone-black is raked from the lower ends of the columns to cause each pile to sink about six inches. The heap of charcoal at the top supplies each column as it sinks. The same process is repeated, so that every portion of the bone-black gradually falls between the red-hot walls, and is raked out from below. The column of bone-black is sufficiently compact to prevent the ingress of much air, and the consequent burning of the carbon which would thence result. The red-hot charcoal as it is raked from below is thrown into metal boxes to cool; it is then sifted to remove the powder which has been formed, and is fit for use again.

The animal charcoal effects not only the separation of the coloring matters, but also that of the excess of

lime present in the sirup, and in the vivification of the spent bone-black this lime of course remains behind. It is proved, however, that the lime does in nowise impair the decolorizing power of the charcoal. It has been supposed that such lime forms phosphate of lime with the phosphoric acid contained in the coloring matters of the juice, and thus on their carbonization gives rise to a charcoal having the same decolorizing power as the original bone-black derived from animal organization. But the gain from this must be trifling.

The kiln made by Mr. CHANTRELL of Liverpool is now becoming more and more extensively used. It is of firebrick. Fig. 558 shows the kiln in elevation. Above is a hot floor, on which the charcoal is dried before it is strongly heated. The hot floor is seen also in the longitudinal section, where it is shown to be heated by the flux which comes from the furnace on its way to the chimney. The kiln represented here contains twelve chambers for the charcoal, each two feet long and three inches broad. In front there are three, and in the side view four behind each furnace door. These chambers or slits receive the charcoal at the top after drying, and, being filled up with it and heated to redness, all the organic matter in the charcoal is destroyed. When this is done, or in about forty minutes, the slide at the bottom is removed, and the charcoal falls into coolers or iron vessels somewhat narrower than the red-hot chambers. Each chamber divides into two coolers, which are exposed externally to the air, and allow the charcoal to become black, removing all fear of burning or uniting with oxygen, when it arrives at the measuring box at the bottom.

The elevation shows the furnace doors, and above them three doors to open into the flues which circulate among the chambers, as seen by the arrows in the longitudinal section. Each door has a spy-hole, which is usually kept covered. It is used to inspect the condition of the flue as to heat and cleanliness. Three perforations between the furnaces at D are holes for conveying away the gases which are generated. On the elevation the iron braces are seen at the side and between the kiln doors. This kiln is said to require much less coal than the iron pipes, saving, according to some, seventy per cent. Certainly we know the greater conducting power of heat possessed by iron. For this reason it is used for cooling, whilst bricks are used for containing the heat. Some persons expose the charcoal to the air some days before using it, believing that it is improved thereby. Many people carefully avoid using it warm. There may be a true foundation in these customs, but some careful observers have looked in vain. It is common in London for the sugar refiners to have no charcoal of their own, but to obtain it from the charcoal burners ready for use, returning it again when it is used. For the use of a ton they pay thirty-five shillings. This may suit the London method of filtering, which is slow; but it will not suit the Lancashire method of rapid filtration. The first may last a week or more; the second only two or three days.

The burning of charcoal may become a great nuisance to a neighborhood, if not watched. The sugar sometimes left in it is decomposed, and a very

Fig. 558.

pungent vapor is sent off, whilst salts of ammonia also are found in it. To avoid these evils, it is needful to wash the charcoal with great care as soon as it has done its work. Charcoal usually contains seven or eight per cent. of carbon, and when this is removed the charcoal is of little value. It is easily removed if heated in contact with air. Its value is about thirteen pounds per ton, or perfectly dry about fourteen pounds. There is a large amount of soft charcoal, which readily goes into dust; hard charcoal is more valuable.

Charcoal is sometimes allowed to ferment, in order to free it of its acquired impurities. This fermentation generally means merely the action of a weak acid—dilute muriatic. It is useful in beet-root establishments, on account of the large amount of lime needed to throw down the substances in the juice. In the sugar, or in the juice of the sugar-cane, no such excess of extraneous matter exists, and no large excess of lime ought to be used. Such at least is the opinion of the writer, and his experience has not been small. Charcoal itself is like a cavern of mysteries, the more it is studied the more wonderful are its secrets. Science has not yet approached the difficulties as seen in practice, and partly overcome.

A mode of renewing the charcoal, by passing heated steam through it, is in actual use in France. The charcoal need not be taken from the filter, but constantly renewed *in situ*. The process may be conducted for a long time, but as far as inquiries have extended, the plan is actually more expensive than burning in kilns.

No substitute for animal charcoal has been found to approach it in value. It must be hard enough to retain its form after years of use and frequent movement. It must also be porous, and must contain fully seven per cent. of carbon.

The sirup after passing through the bone-black filter is in the state of maximum purity. The subsequent processes of the sugar-maker consist in the removal of the water. This is effected by evaporation.

4.—*Evaporation*.—The modifications of the method employed in evaporating are four:—

1. Evaporation assisted by artificial currents of air.
2. Evaporation by fire in open or closed vessels.
3. Evaporation by steam-heat in open or closed vessels.

4. Evaporation by steam-heat *in vacuo*.

The sirup after treatment with bone-black is run into the evaporating or concentrating pan; the shape of this is various according to the method of concentration to be employed. In a patent taken by G. KNELLER the heated sirup in the pan was submitted to the action of currents of cold air, which was blown through it from a perforated copper pipe immersed in the sirup. The currents of air performed the double purpose of subduing the heat of the sirup and of removing the vapor of water which was formed. The apparatus employed by M. HALLÈTE was based upon a similar principle. It consisted of two concentric copper cylinders, so closed at top and bottom with circular discs as to form a cylindrical jacket. This jacket turned upon an axis in an inclined direction, and was heated by a current of steam. The sirup was allowed

to fall upon the surface of the internal cylinder at its upper end. The heated column of air and aqueous vapor in the internal cylinder determined an upward draught, which carried off the vapor; while by the rotation of the jacket the sirup was spread by centrifugal force into a uniform film upon the internal cylinder, thus exposing a great surface to the drying current. M. CHEVALIER devised an apparatus which combines the principles of those of KNELLER and HALLÈTE. The sirup in the evaporating pan is heated by the action of a coil of steam-pipe immersed in it. The pan is provided with a false perforated bottom. Air which has been heated by passing through pipes heated in a separate vessel, is blown by machinery into the pan below the false bottom. It ascends and escapes as bubbles through the perforation of the bottom, carrying with it the aqueous vapor in its passage through the sirup. This apparatus is said to be very effective and rapid in its action, but the fuel required for its working is great. A simpler and equally effective plan is that proposed by Mr. GADDESSEN, which is thus described by Dr. EVANS:—

This gentleman's apparatus consists of an iron or copper pan, having nearly the form of the half of a hollow cylinder, in which is placed a drum or wheel adapted to the shape of the vessel, and formed of a number of metal rods so arranged that the evaporating surface given to the sirup is increased as much as possible. The wheel, half its circumference being immersed in the liquid, is kept constantly revolving, so that by exposing fresh portions of the heated sirup to the action of the atmosphere at each succeeding revolution, the evaporation of the aqueous particles is rendered more rapid than it otherwise would be, while the temperature is, at the same time, in a corresponding degree reduced. The time required to take off a skip in a pan containing one ton of sugar varies from two and a half to four hours, and the temperature of the sirup ranges from 150° to 180°. From the principles upon which this method of concentration is based, it is evident that its successful working will depend upon the degree of dryness of the atmosphere, and upon the rapidity with which the air passes over the surface of the sirup. The apparatus should therefore always, when it is practicable, be placed at the windward side of the boiling-house; at all events it should be beyond the influence of the vapors which arise from the evaporating vessels.

Some manufacturers assert that the revolution of the drum is apt to occasion frothing in the sirup, however pure the latter may be—especially, as is sometimes the case, if the rods on the drum are of wood instead of iron. The advocates of GADDESSEN's pan, on the other hand, maintain that the frothing, when it occurs, arises from albuminous and other impurities in the sirup, and that it may be entirely prevented by the addition of one or two drachms of washed butter or a few drops of fresh olive oil—an addition which, in all sugar boiling, hinders the formation of permanent bubbles, and, in GADDESSEN's process, allows the drum to be worked at a greater velocity, and the evaporation to be thereby accelerated without inconvenience.

When the water is expelled from the sirup by the simple application of heat to the evaporating pan, and without the aid of mechanical means to increase the evaporating surface of the sirup, the heat applied must be greater than when such helps are had recourse to, in order that the sirup may be concentrated in a reasonable time. For this reason, the evaporating pans must be so constructed and filled with the sugar as not to allow the parts of the pan above the liquid to become unduly heated, and to cause thus the caramelizing and blackening of the sirup. Great care must on this account be employed in the firing of such pans. Where open pans are employed, that is, where the sirup is boiled at the ordinary atmospheric pressure, the approach to sufficient concentration for removing to the crystallizing pans may be judged of either by the physical appearance which a portion of the sirup presents when removed from the evaporating pan, or by the temperature which the sirup assumes; for a sirup consisting wholly of crystallizable cane sugar and water, boils at temperatures which are higher, according as the quantity of water it contains is less. The examination of the physical appearances of the sirup for this purpose is called proof by touch. When the sirup is approaching concentration, it presents the following appearances in succession:—

1. A copper ladle dipped into it, inverted and withdrawn in such a manner that the edge of the ladle is horizontal, is covered with a layer of sirup of uniform thickness, which drains off, not in isolated streams, but, for some distance, in a continuous sheet.
2. On taking a pinch of the sirup between the fore-finger and thumb, and depressing the latter, the sirup separates, and the drop on the finger is nearly equal in size to that on the thumb.
3. By the separation of half an inch, a thread is drawn out, which finally breaks below, the end of the thread becomes hooked, and it rises slowly towards the finger.
4. The same thing occurs at a greater distance, the end of the thread is folded back, and gives to the thread the shape of a long ribbon or stick, which rises more rapidly than before.
5. After a greater separation of the fingers, the thread breaks, being very fine at the end, which turns aside and twists up like a corkscrew. It does not fold itself upon the rest of the thread as before, and the thread does not increase in volume, except by the cohesion, which draws the particle towards the finger, which is the only adhering point. A little more concentration prevents the thread from shrinking at all.

The proof by blowing is performed by dipping a perforated copper ladle—the holes in which are about one-eighth inch in diameter—into the sirup, and then, inclining its edge at an angle of about 45°, the workman blows strongly into the cavity of the ladle, whereon, if the sirup be well concentrated, bubbles are formed of half an inch in diameter on the other side of the ladle.

The following table shows the connection between the temperature of the sirup and the amount of water it contains for one hundred parts by weight of sugar. It shows, also, the degrees of concentration at which some of the above-mentioned terms are applied. The table is from DUMAS:—

Temperature. Fahrenheit.	Composition.		Name.
	Sugar.	Water.	
213·8	100	124·66	—
215·1	100	106·81	—
215·6	100	88·96	—
217·4	100	91·11(?)	—
219·6	100	53·26	—
220·1	100	47·26	—
221	100	41·63	—
223	100	36·00	Weak hook.
226	100	28·52	Thin thread.
231	100	25·05	Common hook.
233·6	100	18·84	Strong hook.
246·2	100	—	Ordinary bubble.
248	100	—	Perfect bubble.
234·5	100	—	—
239	100	16·29	—
251	100	—	Small fracture.
263·3	100	10·92	Large fracture.
270·5	100	—	Fracture on the finger.
271·4	100	—	—

It appears from this table that when the sirup has reached 248°, although water continues to be given off, yet the temperature sinks to 234·5°, after which it again rises. If there be no error in the observation, this is probably due to the formation of a definite hydrate of sugar, which requires a higher temperature for its decomposition; but that decomposition being once determined, the water expelled takes up the caloric as latent heat in its conversion into steam, thus depressing the temperature of the sirup.

The danger of caramelizing portions of the sugar, and thus impairing not only the beauty of the product, but, by the formation of noncrystallizable sugar, diminishing the quantity obtained, has caused sugar manufacturers to seek for means by which this evil may be avoided. The vacuum pan of HOWARD answers this purpose completely. It is universally employed in Europe, and to a large extent in the Colonies.

All liquids boil at lower temperatures when the pressure upon them is lessened. The pressure exerted by the atmosphere upon liquids in open vessels varies from fifteen to ten pounds per square inch. In a vacuum no such pressure exists, and, therefore, liquids boil at lower temperatures than in open vessels. HOWARD'S process for concentrating sirups consists in heating them in vessels from which the air has been wholly or partially withdrawn, that is, in more or less perfect vacua. The heat is applied to the sirup in the evaporating pan by means of a pipe containing high-pressure steam.

The following table gives the boiling point of the sugar in a vacuum pan, at different pressures of the air:—

Height of barometer in inches.	Boiling point.		
	Fahrenheit.	Centigrade.	Reaumur.
0·74	115	46·11	36·89
0·86	120	48·89	39·11
1·01	125	51·67	41·35
1·17	130	54·44	43·56
1·36	135	57·22	45·78
1·57	140	60·00	48·00
1·80	145	62·78	50·22
2·05	150	65·55	52·44
2·36	155	68·33	54·67
2·72	160	71·11	56·88
3·10	165	73·89	59·11
3·52	170	76·67	61·33
4·00	175	79·44	63·56

The drawing on next page—Fig. 559—shows the various parts of HOWARD'S pan.

The principles employed in evaporating by HOWARD'S method, namely, the use of steam as heating

Fig. 559.

agent, and the employment of a vacuum, have received several modifications. These are principally those of ROTH, DEROSNE and DEGRANDE, and RILLIEUX.

The modification of ROTH consists in the absence of the air-pump to produce the vacuum. The vacuum is formed by condensation alone, and this condensation is effected in a separate vessel. It has not been found possible to work so entirely free from air. This process cannot be used without some aid from a pump.

The evaporating pans of M. DEROSNE differ from those of ROTH in the shape of the condensing vessel, which in the former's consists of a tube bent like a cracker, the folds of which lie in a vertical plane. Instead of effecting the condensation by water, DEROSNE employs sirup, which, being allowed to flow upon the upper fold of the tubes, trickles down from one fold to another. In condensing the steam in the inside of the tube, the sirup which flows down the outside of the tubes becomes itself heated, and parts with a portion of its water; while the heat of the tube and its vertical position determine an ascending current of air, which removes the vapor of water as it is formed.

DEROSNE's plan has been modified by M. DEGRANDE by the introduction of an air-pump to complete the vacuum, and employing the vapor given off from the sirup in one pan to heat the steam-pipes in a second

one. It should be mentioned that in DEROSNE's apparatus the sirup is allowed to flow from the pan into a closed vessel, so as not to impair the vacuum. The disadvantages of the plans of DEROSNE and DEGRANDE consist in the complexity of the apparatus they require; in other respects an excellent sugar is obtained with great rapidity.

The system employed by RILLIEUX is the same in principle as that of DEGRANDE. The vacuum is formed by an air-pump worked by a steam engine, and a succession of evaporating pans are employed, the sirup of each pan being heated by the vapor from the sirup of the preceding pan, and furnishing itself the vapor for heating the succeeding sirup. Each pan, however, may be connected directly with the boiler. The steam-pipes in each pan do not form, as is usual, one single layer, but they are piled upon one another like the boiler pipes of a locomotive.

5.—*Crystallization*.—Each mould stands over a separate earthenware basin, or over a leaden trough, which conducts to a cistern. When the moulds are filled with the concentrated sirup—the bung being in its place—the sirup after six or eight hours shows signs of crystallization. It should then be repeatedly stirred, so as to equalize the temperature throughout, and to distribute the crystals already formed, from which the subsequent crystallization is carried on. Several patents have been taken out for the purpose of using atmospheric pressure. The small ends of the sugar loaves may be united together, or, in other words, all may meet in a tube which runs along and connects itself with the pump. In

this way they are all readily drained. The loaves are then removed to a warm room of uniform temperature. After twenty-four hours' standing the loaf is set, that is, it has attained a sufficient consistence to admit of draining. It is with concentrated saccharine liquids as with all other saturated saline solutions, namely, that such a solution, during the process of crystallization, deposits crystals which are larger according as the crystallization takes place more slowly. Hence, if the sugar be required in large grains, the sirup should be kept still; if a fine-grained sugar be required, repeated agitation must be employed during the process of solidification. When the loaves are judged to be sufficiently set the bungs are withdrawn from below, and the mother liquid, which is of course a saturated sirup at the temperature employed in crystallization, is allowed to drain off for two or three days. It is a well-known fact that when a solid body separates in the crystalline form from a solution which contains foreign soluble impurities, the crystals are more free from such impurities than the liquid from which they separate. Hence, in the above-formed loaves, the crystals of the loaf are purer than the sirup which runs from them; they would indeed be of the maximum degree of purity were it not for the sirup with which they are still moistened. The next process consists in the removal of this adhering sirup. Formerly this was effected by the method of *claying*.

This consisted in scooping a shallow hollow in the thick and upper end of the loaf by means of an instrument called a bottoming trowel, and filling the hollow with a paste made of fine white clay and water. The water gradually leaves the clay and percolates downwards through the loaf, carrying with it the colored sirup, and dissolving also from the first strata a portion of the crystallized sugar. In its descent, as it becomes saturated with sugar, it acts simply by displacement, forcing out the colored mother-liquor or molasses from below. The fact that in this process a portion of the solid and whiter sugar is dissolved renders this method a wasteful one; it is now but little employed. In the process of *liquoring* the principle of displacement is alone employed. In this method the top of the loaf is levelled, and upon it is poured a saturated or strong solution of colorless sirup; as this sinks down it displaces the colored molasses. When the sirup commences to flow nearly colorless from the hole below, the loaf is allowed to drain, then inverted to distribute the sirup uniformly, and transferred to the drying oven. M. PAYEN mentions the following points in connection with the process of liquoring:—

1. The liquor must be sufficiently charged with crystallizable sugar to dissolve little or nothing in filtering.

2. The density of the liquor must be nearly the same or very little less than that of the displaced sirup; for if too dense it would flow badly: if too dilute it would escape without removing the sirup or molasses adhering to the crystals. To attain this condition the sugars used for preparing the liquor must be more impure in proportion as those to be liquored are so; for saturated sirups are more dense and viscid when they contain non-crystallizable sugar.

3. The crystallization in the moulds must be regular and not too compact; and for this end it must commence and terminate in the same vessel.

4. The temperature of the room in which the liquoring is performed should not vary much, and should be at least 70°. The operation of liquoring is performed as follows:—The crystallization is complete in twenty hours. The superficial crystalline crust is then removed from the base of each loaf with a trowel, and the surface is levelled. These surface scrapings—or rather those of a previous day's work—are added to sirup until the density becomes 67° Twaddell at 60°.

About five pounds of this liquor is poured at one time into each drained mould, containing about sixty pounds of crystallized sugar, which corresponds to ninety-three or one hundred pounds of concentrated sirup, put into the mould. This operation is repeated three times at intervals of twelve hours, and the sugar is then allowed to drain for three or four days. At the end of this time it may be put into casks, and it will be much drier and less alterable than ordinary brown sugar.

Instead of allowing the mother-sirup to drain out by the force of gravity alone, recourse is sometimes had to the pressure of the atmosphere. This is applied in the following manner:—The moulds are rectangular boxes, about six feet long, four feet broad, and two deep; they are called *tigers*. They are provided with false

bottoms formed of wire gauze or perforated plate. When the sugar is set the space between the real and false bottom is exhausted, and the pressure of the atmosphere forces the sirup from among the crystals of sugar into the hollow space. The mass of sugar which has been thus rapidly drained is either dried at once or previously stamped, to give it compactness, into brass moulds. It has been supposed in the above account, that loaf sugar is to be made; if so the filtered part is reboiled and again crystallized, by which means a sugar of an inferior color is obtained. The filtered portion of this second crystallization is also boiled down and crystallized, producing a third quality of sugar. The liquor from this last is the *treacle* of this country, or if clarified, it is the *golden sirup*. By this means the sugar is divided into *fine*, *seconds*, *bastards*, and *treacle*. Lump sugar is not necessarily white, nor is moist sugar necessarily brown. In making any of these sugars, the crystals are not allowed to stand and harden, unless lump sugar be wanted. If lump sugar be not wanted, the rotary machine is used instead of drainage to separate the sirup. At the same time, in the rough management of the colonies, one boiling down is common, the molasses coming from it being used for rum, or perhaps entirely thrown away, as frequently happens in Cuba, far from the coast.

The sugar with the adhering sirup is then introduced into the centrifugal drying machine, which is shown in Fig. 560 succeeding page.

The crude sugar is placed in the cavity as far as the rim extends. On bringing the drum into gear the box is turned round with a velocity of about 1000 to 1700 revolutions per minute. It follows that the contents of the box are forcibly pressed outwards. The crystalline grains are retained by the copper casing, while the molasses is forced through its interstices and thrown off into the outer reservoir. A rotation of a few minutes is sufficient for the drying of a charge of sugar. The machine is then stopped and the sugar is scraped out with a trowel. The sugar so obtained has seldom the brilliant whiteness of loaf sugar, nor does it possess the same compact form; but the immense saving of time effected by the use of the centrifugal drying machine is bringing it more and more into use.

The very large crystals, remarkably distinct and difficult to dissolve, which have of late been manufactured, are made by boiling to partial crystallization in the vacuum pan; drawing off half and adding fresh sirup, this may be repeated to any size of crystals. In countries where the cane is grown, it is usual, to employ the molasses or treacle for the manufacture of rum, or to export it to Europe to the sugar refiners. The coarser kinds of sugar, moreover, which are made from unclarified or imperfectly clarified juice, and which are known as moist or brown sugar, are also bought by the European refiners, who separate the white sugar from the molasses which they contain. A great loss is experienced by the transportation of sugars from the Americas to Europe. This is in part occasioned by the gradual and more complete separation of the molasses which drains off and escapes into the hold of the vessel, such draining being greatly facilitated by the motions of the vessel; but partly and perhaps

chiefly by the escape of the sugar which such motions produce. The whole bulk of a sugar vessel becomes impregnated with sugar, and metallic bodies in the ship which are far removed from the sugar in cargo, become speedily tarnished and corroded, owing

to the deposition upon them of particles of sugar, and the subsequent fermentation and acidification of such sugar.

Sugar Refining.—The great difference in price between coarse and white sugar, the cheapness of fuel

Fig. 560.

and the facilities of making and repairing machinery in Europe, have given birth to its sugar refineries. In the sketch of the preparation of sugar from the cane—Fig. 560—it is supposed that the whole process is carried through at once. But where the crude products from the colonies are bought by the European refiner for purification, his process differs only from the above-described one, inasmuch as he has at starting solid brown sugar or molasses to deal with, instead of the juice of the cane at its natural degree of dilution. The refiner, therefore, at starting has to dissolve his sugar or dilute his molasses to the necessary degree in order to submit it to filtration. The processes which the refiner has to perform depend, of course, entirely upon the nature of the raw sugar with which he has to deal. In most cases the material which comes into his hands has undergone the process of defecation, but not that of filtration, or the filtration where performed has been very incomplete. To dissolve the raw sugar warm dilute sirup is employed. The sugar is agitated with the sirup by means of a flanged wheel worked by machinery, and the product is then pumped up to the top of the refinery. It then undergoes the various processes of filtration through cotton bags and charcoal and evaporation, which have been already described. In refineries the evaporation is always effected in

vacuum pans, and the drying is generally performed by the centrifugal machine.

Abridged description of the Process of Refining.—As conducted in sugar works here, the process of refining consists simply of the following operations:—The bags are cut up and thrown aside to have the sugar washed out of them. They may be thrown away, or they may be sold for paper, according to their value. The sugar is thrown into a pan which will contain from two to three tons of it in solution. Sometimes it is broken up by a spade, sometimes by machinery cutting it with revolving knives. It is heated more or less; some bring it to boiling. Frequently, if not generally, it is treated with a little lime water; this is called defecation, or blowing up. It is then sent through the bag filters, from which it passes into great iron tanks, where it waits till a charcoal filter is ready. It then passes on to the charcoal filter, and from thence to the vacuum pan to be boiled down. It is then set to crystallize. When this is done, it is freed from its liquid sirup or molasses by the centrifugal machine. Instead of being put into this machine, it may be poured into sugar loaf moulds and washed with sirup. This is sometimes called claying, and is made to sound mysterious. Both processes are one in principle, as sugars when put into the centrifugal machine are in reality washed with sirup.

	Beauvé	Fahr.
Defecation takes place at	27	and about 180°
Syrup runs from the charcoal at	27	" 80°
Syrup from first crystals,	40	" 100°
Reduced to 25° Beauvé for boiling to obtain second crystals—		
Drainage from second grain	40	" 100°
Drainage from third grain	34	" 80°
Drainage or treacle at the last	41-43	

Sugar is soluble in one-fifth of its weight of boiling water, and one half its weight of cold water. Six pounds of sirup, containing five of sugar and one of water, deposit on cooling three pounds of sugar, leaving three pounds of sirup containing two of sugar. Sirup containing one of water to five of sugar boils at 238° Fahr., but it is evaporated till the boiling point is as high as 240° or 242°. If evaporation takes place in the open air, this temperature is actually attained; if HOWARD'S pan is used, no matter what variety of shape be chosen for the pan, the vacuum brings down the boiling point as low as to 145°, but on an average we may say that the sugar is boiled down in the vacuum pan at 160° Fahr. In the open air the appearance indicates the condition of the sirups. In this country the vacuum being of necessity used, a specimen of the sugar is removed by the proof stick. This is simply a brass rod, which is driven from the upper part of the side of the vacuum pan down an aperture made of the same size as the rod. When it reaches the bottom, the rod is twisted half round by the cross handle, and opens a communication with the end of the rod and the sirup. In the end of the rod is a groove into which the sugar enters; the rod is half turned again and drawn out, and the entrance is closed as at first. A portion of sugar is taken between the finger and thumb, and the indications are obtained which have been already described. When the sugar is ready, the vacuum pan is opened, and the sugar falls out into a large copper. There are various ways of disposing of it at this period; but in every case it is put into a series of small vessels. If loaf sugar is to be made, it is here heated up to nearly boiling. In some places it is put into pans of earthenware not unlike, or it may be exactly like the sugar loaves, even although there is no intention of making loaf sugar. Sometimes these vessels are made of zinc, and painted; iron has been tried. Sometimes the vessels are very large, containing from one to ten hundredweight of sugar. These vessels are allowed to cool slowly. For fine sugar 90° Fahr. is used, for common 115° Fahr., during which time the crystallization takes place. Every vessel must, of course, have an aperture at the bottom, which is opened for drainage as soon as crystallization has commenced. Each vessel has a drain under it communicating with a general receiver; when the drainage ceases the sugar—in houses on the newest system—is taken to the centrifugal machine, unless, of course, loaf sugar be made. The time of standing is from two to six days. The sugar when crystallized is surrounded with colored sirup, not so pure as the sirup which comes from the charcoal; time and workmanship have produced a dark hue again. It has become exceedingly hard, the crystals being strongly held together, some very dark-colored sirup still remaining. It is removed from the moulds or forms by a pickaxe and spade, or

more frequently by a cutter, which is of the same curve as the inside of the crystallizing vessel, and which, being driven by considerable force, scoops out the sugar readily. In order to remove the liquid about three minutes are required. It is often the case that the sirup has hardened too much, and it is then needful to soften it with a jet of steam, which enters the side of the *hydro*, as the hydro-extractor is technically called. The liquid, with all the impurities, flows off by an underground pipe, and is used again. The first crystallization produces fine sugar; the next, seconds; and the third, bastards. The uncrystallizable treacle is the fourth product. When loaf sugar is to be made, the moulds are of the well-known size, containing about thirty pounds.

Special description of the more complex machines, with some additional details.—In order not to load the account of the processes used in sugar refining with the description of too many machines and minute details, the special parts of the apparatus will be more minutely described in this part of the article, and additional particulars given for those who desire to enter more fully into the subject.

Sugar Mill.—Fig. 561 represents the arrangement of mill and boiling-house as used in the colonies. The size of a sugar plantation in the West Indies varies from one hundred and fifty to two thousand acres, producing from one hundred to five thousand hogsheads of sugar per annum. The boiling-house should be situated in a central position on the plantation, to avoid loss of time in carriage of the canes from the fields to the mill. The mill A—Fig. 561 and drawn to a larger scale in Fig. 554—consists of three heavy cast-iron rollers, about two feet four inches diameter and four feet long, fixed in strong cast-iron frames. The canes are fed from the feeding table, B—Fig. 554—and are squeezed twice between the top roller, C, and each of the two lower rollers, D and E. The megass, or solid part of the cane, after being squeezed passes from the mill by the shoot, F. A trash-turner, G, is placed between the two lower rollers, and under the top one, to guide the canes between the upper and second lower roller. The spaces between the upper and lower rollers are adjusted by the screws, H H; the space between the top and first lower roller should be a quarter of an inch, the second lower roller being set close to the top one. The juice drops into a trough below, from which it runs to the clarifiers, directly if possible; but if the mill cannot be placed sufficiently high to command the clarifiers, a pump is used, worked from the top roller spindle and fixed in a cistern under the trough. The speed found most advantageous for expressing the juice from the canes is at the rate of twenty feet per minute at the periphery of the rollers. The two lower rollers are driven from the upper one by spur pinions, I I I, keyed on the ends of the spindles. The mills are driven by steam—as shown in the drawing—but sometimes water or wind power is used according to the physical character of the country in which it is used. Cattle are also employed to work them in some places, especially on small estates where fuel is difficult to be obtained. In cattle mills the rollers are usually vertical instead of horizontal, being simply driven by yoke arms fixed to the spindle of the

centre roller; the cattle working from the ends of the arms. The rollers, three in number, are fixed in a line with each other, the two outside ones being driven from the centre roller by spur pinions keyed on the tops of

the spindles. The weight of the rollers is carried on hardened steel plates fixed in the framework of the mill; a steel toe being fitted to the bottom of the spindle to bear on the steel plates. The canes are fed

Fig. 561

between the first and centre rollers, the megass coming out on the same side between the centre and third roller, a piece of plate-iron bent to a sweep corresponding to the diameter of the centre roller, guiding the canes round to be squeezed the second time between the centre and third rollers. The juice falls into a trough placed under the three rollers. A cane carrier is often used to supply the canes to the horizontal mill. It consists of two endless pitch chains working over barrels, the upper one being driven from the spindle of the top roller by spur-wheels or another endless pitch chain. On the outer side of the chains are attached boards sliding over a wood framing, with a ledge on each side to keep the canes on the carrier. The top of the carrier is level with the top of the feeding table and extends some thirty feet from the mill. The canes are delivered on the carrier instead of on the feeding table of the mill, which facilitates the work, besides causing the mill to be more regularly supplied with canes than when they are delivered on the feeding table of the mill.

Clarifiers.—The juice, as it is expressed from the canes, runs into the clarifiers, one of which is shown at B—Fig. 561. Two are generally used, one filling while the juice in the other is clarifying. They are generally cylindrical copper-pans with crown or arched bottoms to resist the action of the fire. They are fitted with a large cock at the bottom for running the juice into the first copper. They are set in brickwork at the end of the battery, the flame passing under them previous to going into the chimney, a damper being provided to each to direct the flame under the one that is full. Milk of lime is added sufficient to neutralize the acid in the juice.

The battery is a range of pans, C D E F, with the fur-

nace, G, at one end. The fire passes under the range, and under either of the clarifiers to the chimney. The pans are hemispherical in shape, diminishing in size from the first copper, C, under the clarifiers, to the striking teach, F, in which the evaporation is completed. As the juice becomes concentrated in the pans nearer the furnace, they are filled up from those behind them, until the striking teach is sufficiently full, and the sugar in it concentrated to the granulating point. It is then ladled into shallow wooden vessels, where it is allowed to cool, and from thence it is conveyed into the hogsheads in the curing-house. An improvement in the old system of lading from the striking teach to the coolers is now much used. It consists of a copper pan, H, fitting the inside of the striking teach as accurately as possible. At the bottom of this pan or dipper is a large valve opening towards the inside of the dipper, the valve being worked by a lever, I, over the side, and a chain from the ground. The dipper is attached to a crane, J, which commands the striking teach and a gutter to the coolers. The advantage of the dipper is that the striking teach can be emptied and refilled in much less time than by the ladle, and consequently there is not so much risk of burning the copper and the sugar. A gutter is made in the brickwork at the side of the battery into which the impurities that rise to the surface of the liquor are skimmed. The skimmings—from which are distilled the best rum—are conveyed from the gutter to a tank previous to fermentation. The floor of the curing-house, in which the molasses is drained from the sugar, is composed of a series of gutters which incline to the centre of the building and deliver their contents to a main gutter which communicates with a tank for the molasses. The hogsheads are placed on end over the gutters,

small holes being bored in their ends for the passage of the molasses. The sugar, after remaining in the curing-house about fourteen days, is ready for shipment, and is known in the market as raw or muscovado sugar.

The megass, after passing through the rollers of the mill, is dried and used as fuel for the battery; being better suited for that purpose than any other convenient fuel, as far as heat goes, a very quick fire being required. A saving of fuel is effected by placing the boiler of the cane-mill engine at the end of the battery, so that the products of combustion may pass from the battery through the boiler flues, previous to going into the chimney. A furnace is fitted to the boiler for use before the battery is at work in the morning, and which can be shut off when not required, the waste heat from the battery being almost sufficient to work the boiler for the cane-mill engine.

In the striking teach of the ordinary battery there is a liability of the upper part of the teach becoming overheated, and so making the sugar of a darker color when it splashes up against it, depreciating its value. A pan made so that the heating surface is entirely covered with liquor is used in some places, called a *bascule* or tiltpan. It is a shallow, cylindrical, copper pan, about five feet diameter and two feet deep. It is furnished with a lip to run off the sugar, and works on a hinge under the lip. The pan is set over a fire, and when the sugar is boiled to the granulating point, it is tilted up by a lever and chain fixed to it. The sugar being turned out at once into the cooler, there is not the same risk of burning as in the ordinary fixed pans.

Rectangular copper pans with crowned bottoms have also been substituted for the hemispherical pans with cocks or valves, to empty them from the bottom. They are ranged side by side over the furnace, so that the flame runs under them from end to end; and there being no side flues, the metal of the pans does not become heated, and consequently the quality of the sugar is not injured.

Figs. 562, 563, 564 show a boiling house fitted up with the latest improvements in the machinery connected with the manufacture, for facilitating the process and improving the color and quality of the grain. It is worked wholly by steam heat, as being more economical in the working, and admitting of more perfect regulation of temperature. The juice from the mill, A—as described before—is forced up to the top of the building to the clarifiers by a *monte-jus* or juice elevator, B, consisting of a wrought-iron vessel into which the juice flows from the mill by a pipe and cock. Another pipe is fixed to the top of the monte-jus and rises to the required height, dipping down to near the bottom of the monte-jus; the steam being admitted at the top forces the juice up the pipe. This is more convenient than a pump, is cleaner, and not so liable to acidify the juice. The clarifiers, C C C, used here are hemispherical copper pans, hammered out of one piece of copper fixed by a flange laid off to an outer cast-iron pan, allowing a space between the pans for steam. A copper light course is fixed to the top, the heating surface not being required up to the top of the pan. A valve is attached at the side to regulate the supply of steam, and a two-way cock at the bottom;

the smaller branch being for the clarified juice, and the larger for the scum. The juice in the clarifier is raised to a temperature of 176°. Milk of lime is added sufficient to neutralize the acid in the juice. The heat is then continued till a scum, consisting of impurities present in the juice, has risen to the surface and appears about to crack. The time occupied in this should be about ten to twelve minutes from the commencement of the operation. The steam is then shut off and the liquor allowed to subside for fifteen or twenty minutes, when the scum will be found to remain at the top; some heavy matter, such as dirt, *et cetera*, will have fallen to the bottom, and between them will be the clarified cane juice, clear, and of a pale straw color. The clear liquor is separated from the impurities in the following manner:—At the bottom of each clarifier is a plug, ground into the top of the cock, with a rod and handle above the top of the clarifier. At the side of the plug are holes about three or four inches above the bottom of the clarifier, adjustable by a copper clip, below which all the heavy matter will have accumulated. The clarification then being complete, the cock is first turned on to the smaller aperture until the scum accumulated at the top begins to appear. The cock is then turned to the large way and the plug taken out. The heavy matter at the bottom and the scum formed during the process are conveyed to a cistern, from whence it is placed in bags, and any juice remaining in it is squeezed out, leaving only a small portion of solid matter behind. The clarified juice or liquor, after coming from the clarifiers, is passed through mechanical filters. The kind commonly used are rectangular cases of cast or wrought iron with an internal flanch at the top to support a copper box, about twenty inches deep, to receive the liquor to be filtered. At the bottom of the box a number of holes are drilled and screwed to receive the bells or connections, to which filter bags are attached. These bags are made of twilled cotton cloth, about six feet in circumference and six long, wove without a seam. They are inclosed in a strong open webbing, about eighteen inches in circumference, thus giving a large surface of filtering medium in a small space. The filters are shown at D D D. The liquor is drawn off at the bottom into a receiving cistern, E, to supply the evaporating pan. Steam cocks are attached to the side of the cases for cleansing them after use; and doors are fixed to them for changing the bags. The evaporation is here effected in vacuo, as being most advantageous, the liquor boiling at so low a temperature as not at all to discolor the liquor or alter the saccharine matter in it. The first cost, however, of the apparatus is increased, and alone prevents its universal adoption.

The vacuum pan, F, used for the evaporation of the liquor, consists of a copper pan fitted in a cast-iron steam case, allowing a space between for the steam, and on the top is a copper dome; the copper and iron pans and dome being accurately fitted and bolted together, so as to be perfectly steam and air tight. In order still further to increase the heating surface, a large brazed copper worm is fixed inside the pan. A manhole, with a ground brass cover, is attached to the top of the dome, from the side of which a pipe leads to the receiver or safety vessel, furnished with a glass

Fig 562.

guage and draw-off cock, the use of which is that the attendant may see if the pan primes or boils over ; if it does, the sugar must fall into the receiver, and be indicated by the guage. A pipe from the top of the receiver, with a valve to shut off the communication, connects the pan with the condensers. The pan is fitted with a cock at the bottom for running off the liquor when sufficiently concentrated, namely, at about 36° Twaddell. On the dome of the pan are fixed a barometer ; a thermometer, with bulb dipping down into the liquor ; light and sight glasses for looking into the pan ; an apparatus for testing the concentration of the liquor without destroying the vacuum in the pan ; air-cock for letting in the air when the liquor is required to be drawn off ; and a steaming valve for cleaning the pan after work. Surface condensation is employed to maintain a vacuum in these pans, in

situations where there is not sufficient water to admit of condensation by injection being used.

The surface condensers are here shown, G & G. This process of condensation was introduced and patented by Messrs. PONTIFEX and WOOD of London, who have recently patented a simple and efficient method of connecting the pipes—admirably adapted for the colonies, and all places where skilled labor is difficult to be obtained. The condensers consist of one or more series of copper pipes, fixed to boxes at each end, with partitions to direct the current of the vapor. Above each series of pipes is fixed a trough always kept full of water, and so constructed that the water trickles in a gentle shower, uniformly spread over the pipes, so as to keep them well covered with a thin film of water; the lowest pipe is connected with a small pump, worked by the engine, which draws the condensed

Fig. 563.

vapor from the pan, and any air that may have collected there. The improvement referred to consists in doing away with solder joints at the junction of the pipes with the case, the solder being liable to crack from the unequal expansion of the pipes, owing to the lower pipes being cooler than the upper ones, and the substitution of an elastic joint, which allows for the irregularity of the expansions, without injuring the vacuum; they are also easily replaced, not requiring any mechanical skill, and take up less space for shipment; these pipes and cases being packed separately. The superior economy of water in these condensers, is owing to the condensing water being evaporated and carrying away not merely sensible but latent heat. The ordinary method of condensation is similar to that employed in the condensers of steam engines, when the steam is led into a vessel, where it is brought into con-

tact with a stream of cold water. In this case, as the condensing water must not be allowed to become vaporized, all the heat it absorbs must be in the form of sensible heat, and it is said practically to require about thirty times the quantity of condensing water; but in these surface condensers the vapor which passes off from the surface of the pipes, not only carries off the sensible heat, but it also renders latent a great amount of heat in its conversion into vapor, the quantity of water passing off from the surface being equal or nearly so to the quantity condensed inside the pipes. The water which falls into the trough under the condenser is used over again, the heat of it not materially affecting the action of the condensers.

When sufficiently concentrated, the sugar-liquor is let down into a receiving cistern, H, placed below the pan, from whence it is forced up by the monte-ijs to

Fig. 564.

a cistern, I, above the level of the top of the charcoal filters. The charcoal filters, J J J J, are large, slightly conical vessels, generally of wrought-iron, with a perforated false bottom about an inch and a half from the bottom. A blanket is spread over the false bottom to prevent the charcoal from being carried through with the liquor; some, however, always accompanies the liquor at first, which runs into a separate receiver to be filtered over again. In filling these vessels, the first few inches of charcoal should be pressed compactly down, after which it is packed lightly but evenly, nearly to the top, where space is left to receive the liquor. The object to be attained in these filters, is to remove all the vegetal coloring matter from the liquor, and any excess of lime that may have been added during the clarification, as well as some of the mineral salts, such as sulphate of lime, originally existing in the cane juice. The liquor from the charcoal filters runs into a cistern, K, preparatory to being drawn into the granulating pan.

The granulating is also performed in vacuo, and the pan, L, is similar in its construction to the one before described for evaporation, and a similar surface condenser is applied when there is a deficiency of water. To the granulating vacuum pan a measure is usually attached, so that the attendant may know exactly how much liquor he lets into the pan. There is also a proof stick or instrument for taking a sample of the sugar out of the pan during the concentration, without destroying the vacuum. A slide is fitted to the bottom, instead of a cock, for letting out the sugar when the granulation is completed. The pan is also fitted with light and sight glasses, barometer, thermometer, *et cetera*.

The sugar, on being let out of the pan, drops into a heater, M, a hemispherical pan of a similar description to the clarifiers described before, in order to raise the temperature of the sugar above what it was in the pan, to harden the grain previous to being conveyed to the curing-house. The water arising from the condensation of the steam in the various vessels, passes from the bottom through a condense water box attached to each vessel, in the interior of which box a float and valve are so arranged that the water passes through without letting the steam escape. The outlet pipes from the condense water boxes are carried to a cistern, into which the suction pipe of the feed pump to the steam boilers dips, to be used over again to supply them, a very small quantity of cold water requiring to be added to make up for loss by waste. In some parts of the manufacture, high pressure steam being required, such as for clarification, for the steam engine, and the montejus, it is found better to keep the steam up in the boilers to a uniform pressure, lowering the pressure to the vacuum pans and heaters when the temperature of high pressure steam would injure the quality of the sugar. N represents an expansion vessel for effecting this purpose, and is fitted with one of Messrs. PONTIFEX and WOOD's patent improved valves, by which the steam in the expansion vessel is sustained uniformly at any required pressure. However high or fluctuating the pressure may be in the boilers, the excess of pressure shutting the supply valve to the expansion vessel,

safety and whistle valves are attached to the top, and a gauge on the side to indicate the pressure of steam.

The evaporation of the juice, up to 48° Twaddell, may be carried on in the ordinary battery of hemispherical pans or the improved rectangular ones, as previously described, without being seriously detrimental to the liquor, although the plan last described of evaporating, as well as granulating in vacuo, is most approved. A better method of evaporating than by direct fire heat is by using steam evaporators—the best form of which having the largest heating surface, combined with facility for cleaning, is a rectangular vessel, generally of wrought-iron, at the bottom of which is placed a range of copper pipes as close to each other as convenient. The pipes are connected together by copper bends brazed to the pipes. The entrance of the steam and exit of the condensed water are at the same end of the evaporator, and pass through stuffing boxes, to admit of the pipes being turned up, so as to be able readily to approach all parts of the evaporator to clean them—a point of great importance in the manufacture.

Machinery and apparatus, such as those described in the preceding, and fitted with all the modern improvements are, it is true, costly in erection, but they very soon pay for themselves in the superior quality of the article produced, and the greater return from the same quantity of canes. By employing the strong mills and powerful engines as now manufactured, the canes yield a much larger per centage of juice than previously; and the megass leaving the mill being much dryer is in a better condition to be used as fuel. By applying steam heat, and boiling in vacuo at low temperatures, the color is improved, and less of the sugar is converted into molasses, so that estates which were worked at a loss before may, by the introduction of improved machinery and utensils, be made to yield a profitable return. In colonies where field labor is difficult to be procured, it is especially important to the planter to obtain the most approved machinery, so as to cause as little waste as possible of the raw material.

The machinery of a sugar refinery as worked in Europe is shown in Fig. 565, which represents the elevation of a refinery of the most modern construction, for the conversion of the raw sugar, as imported, to the white loaf sugar of the consumer. The raw sugar, in hogsheads, boxes, or bags, is lifted from the waggon to the upper story of the house by a crane worked by a steam hoist machine, A. The first operation is to melt the sugar, which is usually done in cylindrical or rectangular open pans, one of which is shown at B. At the bottom of the melting, or *blow-up* pans, as they are termed, is a perforated copper worm, and over the worm is a perforated false bottom to keep back any large substance that might be mixed with the sugar. After adding to the sugar a sufficient quantity of water to bring the density of the liquor, when dissolved, to about 44·5° to 46·5° Twaddell, the steam is then turned on, mixing directly with the sugar; whilst being dissolved, bullock's blood—still in some places—and lime water are added to clarify it and neutralize the acid. Mr. FINZELL

Fig. 565.

of Bristol, one of the largest sugar refiners in the world, has patented a modification of the vacuum pan in place of the ordinary melting pans, which he thinks expedites the operation of melting; the sudden expansion of the air confined among the sugar assisting the steam and water in the breaking up and melting of the mass. A movable false bottom is placed over the worm to allow a space for the water between the sugar and the heating surface, and to keep back any extraneous matter. Messrs. FINZELL and ASPINALL have also recently patented a new form of pan for melting sugar, in which the sugar is suspended near the surface of the water in such a way that, as it becomes dissolved, it falls by reason of the greater density of the solution to the bottom of the pan, leaving the next stratum to be acted on by water not so saturated with sugar; whereas, if the sugar lies at the bottom of the pan, the water in immediate contact becomes thoroughly saturated, and, remaining at the bottom by reason of its density, retards the dissolution. This is, however, compensated for by a large stirrer, universally used in blow-ups. On emptying the hogsheads, *et cetera*, a portion of sugar is left behind sticking in the crevices of the staves; this is removed by placing the hogshead in a *steamer*—when, the steam being turned on for a short time, all the sugar is washed out of the hogshead, and drops mixed with the condensed steam to the bottom, from whence it is conveyed to the melting pan.

From the melting pan, B, the liquor is drawn off to the bag filter, C, similar to those described before for the cane juice. The liquor then runs into the receiving cistern, D, with a coil of copper steam-pipe at the bottom to increase the temperature previous to entering the charcoal filters. The charcoal filters, one of which is shown at E, as generally used in refineries, are cylindrical vessels of cast-iron or copper, about five feet diameter, and twenty to thirty feet high; the greater the depth of charcoal the liquor has to pass through, the less coloring matter is left in the liquor. The filters are furnished with a perforated false bottom, a blanket being spread over it to prevent the charcoal from passing through with the liquor. The tops are generally closed, to admit of a head of liquor above the charcoal to accelerate its passage through the filter, a manhole being cast in the cover to let in the charcoal, and another at the bottom to get it out when required to be changed. From the filters the liquor runs into a cistern, F, placed on the basement or *fill-house* floor, from which it is drawn up into the granulating pan, G. A vacuum pan is used for this purpose similar to the one before described for granulating the sugar from cane juice; only in this drawing the condensation is shown, effected by the injection of cold water into a vessel when it meets the vapor from the pan: this method is adopted when water is abundant, the outlay not being so great. The sugar, when granulated, is let down into the heater, H, by a slide in the bottom of the granulating pan, the sugar requiring the temperature to be increased in order to harden the grain; it must also be well stirred, to mix the grain thoroughly previous to being ladled out into the moulds. This operation of lading is usually performed in copper

filling-out basins, into which the sugar is ladled from the heater. When practicable, labor may be saved by raising the pan and heater up to a floor above, so as to draw the sugar off from the bottom of the heater by a slide.

CENTRIFUGAL MACHINES.—If the sugar is intended to be in the form of crystallized, from the heater it is put into the centrifugal machine, which consists of an outer cylindrical case, in which revolves at a very high speed an inner vessel perforated round the circumference, into which the sugar to be dried is placed; the centrifugal action from the velocity causes the sirup to pass through the perforated circumference into the outer case, from whence it is drawn off, leaving the crystallized sugar behind. By this means much time is saved in the draining of the sugar. The same effect is sometimes attained by connecting the bottoms of the moulds to a pipe communicating with an air-pump, when the pressure of the atmosphere acts in the same manner as the centrifugal force; or the sugar is placed in a large box fitted with a perforated false bottom, from which the air is exhausted. This latter plan is often adopted with much success in the West Indian Colonies.

The moulds, I, I, I—Fig. 565—into which the sugar passes from the heaters, are of a conical shape, and usually made of sheet-iron; the lower part or apex of the cone being of cast-iron, with a small hole for the sirup to drain through. They are either painted or galvanized inside and out, to preserve them from rust; they are made of different dimensions, according to the size of the loaves required and the quality of the sugar, and are named respectively—loaves, titlers, lumps, and bastards. From the fill-house the moulds are conveyed to the various floors, which are heated by steam-pipes to a temperature of 75° to 80° Fahr., to facilitate the drainage. The moulds are ranged all over the floors, with the points of the moulds resting on iron or earthenware pots, to receive the sirup drained from them. After standing some time till their own sirup drains from them, fine liquor, consisting of a saturated solution of pure sugar, is poured on the top of the moulds, thus, as it percolates down the loaves, washing away with it the impurities remaining on the sugar, which would otherwise adhere to the surface of the crystals. After this the loaves are taken out of the moulds, the lower end is cut to a point in a nosing machine, as it is called, and the top trimmed off by a machine with revolving knives. The ends so cut off are not of equal quality to the centre of the loaf, and are melted over again. The loaves are then papered up and further dried in a stove, J, which is heated by steam pipes at the bottom, and fitted with shelves on which the loaves are placed. After drying they are ready for the market. The moulds are lifted from one floor to another by a machine called a mould-hoist, which is driven by the engine. The mould-hoist, as made by Messrs. PONTIFEX and WOOD, is shown at K, K, and consists of two endless pitch-chains working over pulleys fixed under the fill-house floor, and at the top of the house; between these chains are slung cradles, with rings adapted to the various sizes of moulds used in the house. Holes are cut in the various floors

sufficient for the passage of the moulds, which are readily placed in and taken out of the cradles as they pass up or down. The cradles are slung upon axes, so that the moulds turning over the drains remain in the same position, thus preventing the risk of accident in case the attendant should omit to take them out as they pass him, in which case they only make the circuit with the chain, and are taken out the next time they come round to the floor on which they are required.

The charcoal, after it is removed from the filters saturated with coloring matter, is dried, and then reburnt. The retorts of cast-iron or kilns of clay are so constructed that the charcoal, when at a red heat, does not come in contact with the atmosphere, which would destroy it. The charcoal reburners, as arranged by Messrs. PONTIFEX and WOOD, are shown in Vol. I. of this work, page 340, under the article BONE-BLACK. L is a cistern for water, and M a cistern for fine liquor, a pipe from which runs down the house, with a cock at each floor. This is used for washing the impurities off the sugar crystals in the moulds, as before described.

M. ALFRED FRYER of Manchester has been for some time at work with apparatus which, if successful, will greatly alter the sugar manufacture. He believes it is a wasteful mode of procedure to attempt to purify sugar in the colonies, even to the smallest extent, the facilities for doing so here being much greater. His method is designed to dry the cane-juice rapidly down into a hard concrete, and so to import it into Europe. In the concrete form, and almost free from molasses, it will not decompose, and the enormous waste of more than half the sugar will not take place, the loss in the European refineries being considered large at six or seven per cent.

BEET-ROOT SUGAR.—In Germany and France cane sugar is extracted in large quantities from the beet-root. The beet-root is a biennial plant, native to the South and South-west of Europe. It appears to have been introduced into the Netherlands during the possession of that country by the Spaniards, and to have thence passed into France, Schleswig-Holstein, Germany, Sweden, England, *et cetera*. There are many varieties of the beet, but that specially prized by the beet-root sugar manufacturer, and therefore chiefly cultivated in those countries where this branch of industry is pursued, is the Schleswig beet, or white beet—*Beta alba*—called also from its qualities the sugar beet. When the leaf-buds appear above the ground, the leaves thrown off sometimes rise very high before spreading; sometimes they spread almost immediately above the surface of the ground. This variation, which is partly hereditary, partly conditioned by soil and other circumstances, gives rise to a considerable difference in the quality of the sugar which is extracted. For as the thick and upper end of the tapering root is, during the growth of the plant, projected a little above the surface of the ground, the exposed portions are acted upon by the light, and the otherwise white root is thereby turned green owing to the formation of chlorophyll. But where the leaves spread out on emerging from the ground, the root is

shaded and preserved from such colorization. The Quedlinburg beet has a shade of red on its outer coating, and a species of a yellow variety has been recommended on account of the greater quantity of sugar that exists in its juice. The root of the beet contains water, cane sugar, vegetal fibrin, and fat, gum, coloring matter, pectin, together with the carbonates, chlorides, sulphates, nitrates, phosphates, oxalates, malates, *et cetera*, of potassium, sodium, iron, lime, and magnesia. The water varies from eighty to eighty-eight per cent. of the whole root. The solid matter—twelve to twenty per cent.—contains from four to six per cent. of vegetal fibrin; the remainder is cane sugar, with the other constituents. The length and straightness of the healthy beet points to a deep soil as the one appropriate to its cultivation, while the large quantity of water limits its growth to tolerably moist localities. An over-rich soil, however, is harmful, on account of the introduction into the plant of too much of the mineral constituents. Two or three of the seeds of the beet-root are set by means of a hand hoe, about a quarter of an inch below the surface, at regular intervals of between thirteen to sixteen inches, and covered with earth. If, in consequence of a short heavy rain succeeded by dry weather, the surface of the earth becomes so hardened that the young plants are suppressed, and the prospect of a sufficient crop is lost, the land should be reploughed, and a fresh sowing performed. The amount of sugar contained in the beet varies with its size, the smaller plants containing more sugar in proportion than the larger ones.

It has been found that—

Beets weighing $\frac{1}{2}$ pound contain	13	per cent. sugar.
" " $\frac{3}{4}$ " "	11-12	" "
" " 2 " "	8-10	" "
" " 3 " "	6-7	" "

Nevertheless, on account of the greater mechanical trouble of working the smaller beets, the larger are esteemed most. The tapering point of the root and the thick and higher end also contain less sugar than the central portions; this is especially the case with the thick end when it has grown above the ground and become colored by exposure to the light. During the growth of the plant, which lasts about four or five months, the soil must be turned by the hoe four or five times, the first hoeing being performed soon after the appearance of the young plant. The following rotation of crops is said to be favorable for the cultivation of the beet—1. Barley or wheat—with manure. 2. Beet. 3. Oats—three fields being kept under crop. If four fields be employed, clover may be advantageously introduced after the beets.

The beet, as before stated, is a biennial plant. During the first year of its life the root is developed to its full size, and secretes the whole amount of sugar which, in the natural life of the plant, furnishes the material for the growth and maturity of its upper part. It follows that when the plant is cultivated for its sugar, it is for this purpose ripe when its first year's stage of development is complete. The time required for this depends upon that of the sowing, and upon the seasons. Its criterion is the commence-

ment of death in the leaves. When ripe the beet-roots are dug out, the mould gently shaken off, and the heads cut off, together with as much of the root as shows the presence of leaf buds. As the action of light is detrimental even to the exhumed roots, the latter must be covered quickly. If the quantity be small they may be covered with the leaves which have been cut off. It is more usual, however, to pile them in heaps on the ground, to hinder the evaporation of their water, and to protect them from light and frost by covering the heaps with a thin layer of earth. These mounds are sometimes sprinkled with water, which is taken up by the roots, restoring to them their plumpness and crispness which they have lost in a dry season.

The amount of beet root obtained on a given space is, according to BOUSSINGAULT, in—

PAYEN gives the following as the chemical constitution of beet root:—

	Per cent.
Water	83.5
Sugar	10.5
Cellulose	0.8
Albumen, casein, and nitrogenous matters	1.5
Salts, &c.....	3.7
	100.0

Under salts, *et cetera*, are included malic acid and gum, nitrogenous substances, fatty matters, aromatic substances, coloring matters, essential oil, chlorophylle, malamide, oxalate and phosphate of lime, phosphate of magnesia, chloride of ammonium, silicate, nitrate, sulphate, and oxalate of potassa; oxalate of soda, chlorides of sodium and potassium, pectates and pectinates of

lime, potassa and soda, sulphur, silica, oxide of iron, *et cetera*. The sugar is entirely in the state of cane sugar.

It has been shown, however, that ammoniacal salts do not exist ready formed in beet juice, but are the product of decomposition eliminated, especially when lime is added.—*Michaelis*.

Lactic acid is readily formed by the decomposition of beet root sugar in its juice, and some persons find mannite, although others are not able to do so. A gummy substance is also produced, probably similar to that found in cane sugar refineries, when the sugar has been too long boiled and worked with.

The beet is grown in temperate climates, and it requires a good deal of moisture.

BOUSSINGAULT gave the following analyses of French beets:—

Where grown.	Time of taking from ground, <i>et cetera</i> .	Per cent. of dry matter.	Water.	Sugar.	Ligneous fibre and albumen.	Pectin?

It has been found that beet with a large amount of juice containing many salts, gives little sugar; either the sugar is not formed, or it is combined with the salts and rendered useless. Manures with a large amount of soluble salts must therefore be avoided; farmyard manure, for example, must not be used in large quantities. Neither a very wet soil nor a very dry one suits the beet root. The Silesian beet is most admired; its juice has a specific gravity of 10° to 15° Twaddell—105° to 107°—and is very pure. It is not a large root.

The amount of juice obtained is from seventy to eighty per cent. of the beet.

The roots, after their extraction from the earth, have to be cleaned and the bruised or diseased portions extracted. For the first purpose they are brought into

Fig. 566.

a horizontal cylindrical cage, which rotates round a horizontal axis, and is turned by machinery.

After washing, the roots are examined by women and the unhealthy parts cut out, the smaller side-roots cut off, *et cetera*.

In order that the greatest quantity of juice may be extracted, the roots have to undergo a thorough trituration, the purpose of which is to destroy the cells and other texture, and to allow the free escape of the juice. The accompanying figure shows the construction of a trituration mill of this kind.

The macerated beet-root appears as a white thin emulsive liquid, and contains naturally the whole of

Fig. 567.

the constituents of the root. The soluble portion is separated from the insoluble by pressure. Woollen, linen, or, for the reason mentioned in the manufacture of cane sugar, cotton cloths or bags are employed to hold the juice. When cloths are used the process of *packing* is as follows :—A plate of iron of the size which the cake is destined to have is placed upon the press-table—see below. Around this plate a movable wooden frame is placed, of the appropriate depth. The frame and plate are covered with the cloth, which is smoothened into the edges and corners of the box so formed; the corners of the cloth being of sufficient length to cover the box again when folded back. A measure of the crude juice is then poured upon the cloth smoothened down by the hands, and the corners of the cloth are folded back upon it. The wooden frame is then removed; another plate is placed upon the top of the first cake, the frame adjusted round it, and the same process is repeated. In this way a pile of cakes, inclosed in cloths, is formed, alternating with iron plates. Sometimes, instead of iron plates, a disc of plated osier, or a series of rattan canes lightly bound together is used. The latter contrivances are less likely to break the bags when the pressure is applied, but the juice is not so perfectly expressed as when metal ones are employed. When bags are used they are filled with the juice, the mouth squeezed together, and the whole turned over upon the plate, so that during pressure the mouth is held together.

The piles of cakes are next submitted to pressure, usually that of a hydraulic press. The piston of the press is made to descend and to squeeze the pile between itself and a firmly fixed metallic slab, rather larger than the cakes. The surface of the press table is nearly on a level with the top of the slab. The press table is surrounded by a rim, through one part of which a hole is cut, connected with a pipe for carrying off the juice. It has been proved that the best presses

leave at least twelve per cent. of the theoretically extractable juice in the cakes. A portion of this may be recovered by steeping the cakes which have undergone the first pressure, in a shallow vessel of water, or submitting them to the action of steam, and subjecting them to a second pressure. But even then by no means the whole of the sugar is separated. Moreover, the greater dilution of the juice so produced increases the expense of its subsequent working. Perhaps the centrifugal drying machine may find an application to this end; or perhaps the passing of long bags of the juice through cane crushing-mills might extract the juice more effectually. But the importance of the perfect separation of the sugar is not of so much moment as is the case with canes, because the spent cakes are generally used in beet-root sugar manufactories as food for the cattle employed on the estate, and their value for this purpose is greater the more sugar they contain.

An exhaustive method for obtaining the juice from beets has been proposed, in which the roots are sliced and macerated without destroying the integrity of the slices. The weak juice thus extracted is employed for macerating a fresh portion of slices, and so on until the extract is sufficiently strong for defecation and filtration.

Probably on account of the greater quantity of albuminous matter contained in the beet over that in the cane; in part, also, on account of the greater dilution of the natural sirup—the oxidation and fermentation of the former proceeds more readily. Hence extraordinary care must be taken not only to submit the extract from the beet as speedily as possible to the subsequent operations, but the press table, *et cetera*, must be thoroughly cleaned after each pressing, and the bags or cloths perfectly purified.

The processes for defecating the juice of the beet-root, are so analogous to those already described with the juice of the cane as to need no special description. The scum is submitted to pressure in a screw press, in order to separate the juice which it retains mechanically.

The employment of bone-black, also, resembles almost completely its use with cane sugar. In the beet-root sugar manufacture, however, the filtering cylinders have usually a longer and narrower form than is the case with cane sugar.

Perfectly pure sugar made of beet cannot be distinguished from perfectly pure sugar made of canes; but the imperfectly purified sugars may be distinguished—first, by the analysis as shown in the composition of the juices; and second, by the taste; which is in the case of the beet-root bitter and unpleasant; in the case of the cane sugar extremely sweet, with a pleasant vegetal aroma.

When beet is taken from the ground, it is used at once for sugar; if not used it rapidly germinates, and the sugar diminishes. For this reason SCHUETZENBACH introduced the method of slicing the beet in small pieces and drying it rapidly. When dry it may be preserved. When this plan is adopted, the manufacture may be carried on during the whole year, instead of during a few months only, or from October to March.

By the process of SCHUETZENBACH three hundred kilogrammes of beet are dried every twenty-four hours on a square metre, losing eighty to eighty-four per cent. of their weight. When used it is dissolved into a juice containing thirty-eight to forty-two per cent. sugar at 42° Twaddell, so that there is much less of water to be evaporated than with the green juice. The dried beet is macerated in a closed vessel.

100 kilogrammes of beet give 18 kilogrammes dried beet.

100 kilogrammes of dry beet cost 11 francs 11 cents.

M. SCHUETZENBACH has now made an immense establishment in Galicia. It is calculated to produce forty million kilogrammes of sugar yearly. There is a central sugar refinery and fourteen drying establishments in a circle of seven leagues, in order not to carry the wet beet far. He obtains a dry produce containing fifty per cent. of sugar. It is dissolved in closed vessels, and gives a juice of 52° Twaddell. He obtains six per cent. of sugar from the root. Such an establishment keeps a large circle of ground occupied.

It has been said that it is better to cut the beet into cubes. This plan is not adopted at Waghäusel, one of the most complete establishments, and certainly their slices being thin must dry readily. The plan adopted there is to dry for preservation; this is done in six hours on the wire gauze. Then when making the solution, it is at first obtained at 32° Twaddell, and boiled in vacuo down to 41.5 Twaddell, lime water added, boiled half an hour to remove ammonia, and kept alkaline with lime.

The establishment of Waghäusel, near Carlsruhe, employed in 1855 three thousand people; twelve hundred of these were in the drying department. One drying department was at the works, and six others at different distances. The works covered twenty-five morgen of land—about twelve acres. There were in it one hundred horses, one hundred cattle, and from thirty to forty pigs. A hundredweight of raw roots cost the establishment seven-pence. There were nine cylinders for refined sugar, and thirteen for commoner, twelve feet by six. There were twenty infusing vessels, twelve to fourteen feet deep and seven wide. The dry beet contained forty-six to forty-seven per cent. of sugar. Five per cent. were lost in making; by the old way the loss averaged eleven per cent. The capital was about eight million francs.

Maple Sugar.—In the Western State of North America, a great portion of the sugar required for home consumption is extracted from the maple. The season at which the collection of the juice takes place is the early spring—February, March, and April, when a light snow is on the ground. The trees most fit for tapping are those which have reached the age of twenty to thirty years. At the south side of such trees two or more holes are bored about four or five inches apart, three-quarters of an inch in diameter, and about two feet above the ground. The holes run

radially into the tree, and are inclined upwards, penetrating the inner white bark to a depth of about half an inch. Into these holes tubes of elder-wood are inserted. The upper portion of the part of each tube which is in the tree is slit off, so that it forms a semicylindrical canal or trough. Troughs are placed below the projecting ends of the tubes to receive the juice as it flows out. The average yield of a tree is about one quart in twenty-four hours. A tree may be tapped for twelve years in succession, the average yield being between two and three quarts annually. The crude juice is usually boiled down without defecation or filtration in copper cauldrons, which may contain fifteen or eighteen gallons. When the examination of the concentrated juice shows incipient crystallization, it is poured out into shallow moulds, about two inches in depth. When set, the sirup is usually ladled out of a depression made in one portion of the cake. This maple-sugar sirup, which corresponds to the molasses of cane-sugar, is, however, more highly prized than the sugar itself; it has a delicate aromatic smell and taste, and is greatly sought for making confectionery. The sugar sells at the rate of fourpence per pound. Some years ago enough cake maple-sugar was manufactured in the State of Vermont to inclose the whole State with a wall of sugar eight inches high, and eight inches in thickness. The North American Indians push the evaporation of the juice rather further than the whites, and after the removal of the sirup, the cakes are chopped up for the market.

SUGAR OF STARCH AND WOOD.—Crystallizable sugar is converted by boiling and by acids into glucose or grape sugar, a substance difficult to crystallize. Sulphuric acid converts cellulose, inulin, starch, sugar of milk, straw, sawdust, and such materials, into dextrin and sugar. BRACONNOT obtained from 20.4 of rags 23.3 of dry sugar. Cotton and linen being nearly pure cellulose, would give more than sawdust; about one hundred and forty parts of strong acid are used to one hundred parts of cellulose of rags, cotton, *et cetera*. The change is at first into dextrin—see STARCH—then into the sugar.

Sugar is made from starch by boiling it with water acidulated with one per cent. of sulphuric acid. The conversion takes place in half an hour. The amount of starch is about fifty per cent. of the water. At the same time the quantity is varied, as given by KNAPP that two and a half of sulphuric acid is used to one hundred of starch, and three hundred to four hundred of water. Makers are not precisely agreed as to the time, but it is different according to different degrees of solution. The sulphuric acid is removed by lime. The juice, clarified, is boiled down to 105° Twaddell, and crystallized in flat vessels. Crystallization commences in about a fortnight. The sugar is then drained and dried. This sugar is seldom sold as such. It is manufactured for conversion into alcohol.

The conversion of cellulose and starch into sugar, by the action of sulphuric acid, giving to them some of its water, may be better understood by examining the composition of both, as already given.

CAUSE OF THE LOSS IN THE MANUFACTURE OF CANE-SUGAR.—*Decomposition of the Juice.*—The albu-

minous matter in the juice is the chief if not the only cause of its rapid decomposition, and this is promoted by a heat which is not less than 80°, as the liquid flows from the crushing mills. Lactic acid in the case of beet juice is abundantly formed, and a viscous substance which has no sweetness. At the same time, also, there is formed a little mannite. An enormous loss of sugar is known to occur from this change of the juice. The one to two per cent. of alkaline salts can scarcely be said to act prejudicially to any extent. There is no known way of removing them.

To prevent the decomposition of sugar, especially in the case of Colonial juice, in warm climates, it is important to use an antiferment. PROUST proposed sulphite of lime in 1810; and DUBRUNFAUT took a patent for using sulphurous acid in 1829. MELSENS of Brussels has lately proved the great value of bisulphite of lime in the manufacture of beet-root sugar. The use of this is becoming general for beet-root. It would, no doubt, be found still more valuable in the Colonies, if no unlooked-for harm was occasioned; although care must be taken not to send the sugar over with sulphites in it. The bisulphite of lime resists the coloring of the juice, and even removes some of the color. Acids readily remove the color of sugar; but such color returns as soon as neutralization takes place. MELSENS believes that by means of this salt he will be able to reduce the molasses so much, that he will not remove the salts in solution in it as now, but by taking out ninety per cent. in a crystalline form, he will return the most of the salts to the earth. The small amount of molasses left could be returned to the pressed out beet before using it as food for cattle. The bisulphite of lime does not destroy the quality of the beet as food. LUDERSDORFF prefers sulphuric acid, afterwards to be neutralized by lime.

It is well to add that a French commission examined the action of bisulphite of lime on cane juice in Guadeloupe, and found that the amount of good well-grained sugar was diminished by it. If they used it as acid, as some do, it is not surprising.

KUHLMANN proposed to prevent the decomposition of sugar by adding an excess of lime, and then throwing it down with carbonic acid. This is again brought forward by M. ROUSSEAU. Three to four times the usual amount of lime is added, making a sugarate of lime; when the juice has reached 131° Fahr. the lime is added, mixed with six times the amount of water; the temperature then is raised to 180° or 190°, and the liquid filtered. Carbonic acid is added, a voluminous precipitate takes place, and the juice is now put on the charcoal filter without removing the chalk. M. ROUSSEAU had it brought before a commission of the French Academy, which reported a favorable result, but considered that the alkalies would act injuriously on the compounds of lime and organic matter not precipitated. To avoid this ROUSSEAU adds ammonia, which is converted into carbonate. The carbonate of ammonia decomposes the combination of the lime, and carbonate of lime is thrown down, leaving ammonia free. But this addition of ammonia is no improvement, and indeed the whole objection is a most uncertain one.

KUHLMANN believes that the free alkaline salts are hurtful, but has found it impossible to remove them by means of strong acids, or by sulphate of magnesia, sulphate of ammonia, or chloride of ammonium. He prefers phosphate of ammonia.

This process—one cannot speak for the phosphate of ammonia, but only for the carbonic acid—is a good deal used in France.

MAUMENÉ says that if lime is added in quantity sufficient to form three of lime and one of sugar— $3 \text{ CaO C}_{12} \text{ H}_{11} \text{ O}_{11}$ —the sugar is preserved, and nitrogenous matter falls with the lime. However this may be, if boiled with the lime the color is rapidly deteriorated.

Precipitation.—Attempts have been made to precipitate sugar from its solutions. DUBRUNFAUT and R. DE MASSY have a process depending on the union of sugar with baryta. Caustic baryta is added to the sugar till it is all thrown down. A pure compound of baryta and sugar falls, and this is decomposed by carbonic acid. It is not at all proved that all the sugar can be thrown down in this way; it is said only to be done at a boiling heat. NICKLÈS says it cannot be done with uncrystallizable sugar.—See further in accounts of *Patents*.

USES, PHYSIOLOGICAL EFFECTS, AND IMPURITIES.—Sugar exists in the juices of many plants, and is in part the food of many animals. As an article of food it has highly fattening properties, and as such it must be considered as serving mainly for the production of warmth in the body. Animals which eat it appear sleek and comfortable, and it tends to promote digestion. At the same time there are many persons who cannot use it as food to any great extent, on account of its inclination to produce acidity. The negroes, and even whites, who suck the sugar cane are not found to be troubled with these symptoms, whilst the teeth of the negro never suffer from the constant use of the sweetest liquids. Such, however, is not the case in England, where a great amount of sugar is found to be hurtful to the teeth. It is perhaps scarcely correct to say this of sugar in the diet, as it is not well known that the same effects would be produced by sugar used in abundance—in pies, for example—as would be produced by sugar taken alone and long retained in the mouth. Persons engaged in sugar works are in the habit of eating sugar very frequently. With some it is a part of their duty, as the value is to some extent measured by the taste; but whether as a duty or a pleasure, such persons are almost invariably doomed to lose their teeth at an early period. It may be said that sugars, until dried or thoroughly crystallized, have a certain amount of acidity in them; but this is in general too small to stand as a reason: much more acid is taken in other species of food. There can be no doubt that sugar in large quantities peculiarly affects the digestive organs, and causes also a distinct taste, other than sugar, to be perceptible some time. The cause may be that as an article of food it does not associate well in large quantities with the food used in this country. But, again, its valuable qualities are many, and the amount fitted for individuals must be found by experience.

The excessive use of sugar, that is, to the extent, with a healthy man, of about a pound per day, produces effects not apparently much studied. One effect is a tendency to giddiness, without any observed additional inconvenience. It is possible that this may arise from the large amount of carbonic acid generated during its decomposition, causing at the same time frequent eructations.

When the throat is irritated, a solution of sugar slowly flowing over the surface prevents irritation and allays coughing. Sugar and treacle are valuable for covering burns, acting chiefly, as Mr. CROMPTON of Manchester believes, as non-conductors of heat. It is sometimes used in a powdered state for ulcers or rather proud flesh, and for specks on the cornea. It has a considerable power of reducing metallic oxides, and has been used as an antidote for poisoning by metallic salts, such as those of copper; mercury, silver, gold, and lead may be included; but this action has been referred more to its physical than to its chemical properties. It is highly antiseptic, no doubt, because it covers from the atmosphere. It is much used in pharmacy for imparting flavor to bodies, and to conceal taste. It is also found useful for giving form and consistence to some medical substances. It is employed as a medium of bulk to convey smaller substances, as in opium, lozenges, *et cetera*, and notably so by the homœopaths, whose medicines may sometimes be distinguished from sugar. Many animals delight in it. Horses put their noses into the sugar bags, and even suck them, whilst the fowls fight for the fallen pieces.

Sugar is also employed for fermentation. Indeed, properly speaking, it is the only thing used for fermentation; but sugar from the cane, and still more the less crystallizable portion, is now considerably used. It has been employed for the purpose of making oxalic acid by oxidation with nitric acid; but starch or cheaper substances are more commonly employed. Enormous quantities are used in preserving fruits. Preserved fruits are becoming daily more and more accessible and more used. Formerly fruit was preserved only by such careful and well-to-do housewives as could spend some considerable time and money on the luxury. Now the conservation forms a branch of industry or manufacture. Marmalade and preserved oranges are sent from Scotland in great quantities, and are everywhere prepared. Preserved fruit is also sent from various parts of Europe, especially the shores of the Mediterranean, and it has begun to appear at our dessert tables after arriving from the East and the West Indies. England, as usual, takes up this manufacture with great vigor. One house made a small experiment last year with thirty tons of preserved plums, and finding it successful made next year a hundred tons. The preserves were of an excellent kind, and cheaper than those made by the usual methods in smaller quantities.

The amount of sugar used in the form called sweetmeats, comfits, and bonbons is very great, and more so on the Continent, according to accounts, than here. At the same time, although one finds in France, Germany, and Italy some very handsome confectionery shops, it strikes the Editor that the amount of comfits in

them is very small, and the variety very limited. The sugar may be pure and unadulterated with arsenic and sulphate of lime, or any other noxious or poisonous substance; but the shops seem to depend a good deal on their sale of beverages, and in some places on their restricted number. No country offers such great varieties of excellent sugar sweetmeats as England, or in such rich diversity. In China the variety is said to be very great. The only fault in England is that there exist so many qualities to suit the purses of every man, rich and poor. The inferior qualities are mixed with flour. This, of course, diminishes the sweetness. This would be a small evil, if the makers did not sometimes use instead of flour sulphate of lime or plaster of Paris. Even this, however, is innocent in comparison to the coloring matters used at times. Sweetmeats are colored by ignorant people with common paints of any kind that come in the way. These are painted roughly on the sugar. Some of them contain copper, some arsenic and copper, and some lead. Several cases of death have occurred from the use of such substances; and there can be no doubt of the propriety of a surveillance over the manufacture or sale of articles liable to be so abused. The best confectioners use only innocuous colors, and these vegetal.

The unfiltered sugar, or Muscovado, as it comes from the Colonies, contains many impurities, and should never be used. Many peculiar species of beetles are found in it. One especially infests abundantly all sugar-houses. But the *acarus sacchari* is the animal that, of all others, is the most to be avoided; it is not found in filtered sugar. It is an animal somewhat like an itch insect, and a drawing would not be pleasant in an article on sugar. The grocers' itch is in all probability produced by the handling of Muscovado sugar, and the attacks of this insect. Dr. HASSALL advises the use of refined sugar only. The Editor is able to state that, in Lancashire at least, purified or filtered sugars, of various shades of color, are everywhere to be had, and they are as free from insects as the purest white lumps.

Sugar itself for domestic purposes is not now adulterated, or very rarely. There was a time when sand was used to adulterate the brown qualities; but such a practice would not now be tolerated for a moment. A very ingenious adulteration came into vogue for a while; but the Editor believes it is not resorted to now. It was the custom of using starch, or starch made into gum. When this is used in tea or coffee it is not readily distinguished from true sugar. If starch is employed it is readily found by dissolving the sugar in cold water, in which the starch is not soluble. If British gum be used it is less easily detected; it has small granules, not hard and crystalline like those of sugar, and is soluble in cold water. It also becomes gummy in drying, instead of becoming sirupy, and then crystalline like sugar. This adulteration cannot be made with pure white sugars. A microscope assisted by an ordinary good taste is perhaps the best guide to its discovery. The most general use of sugar is for sweetening tea, coffee, and chocolate; but it is also largely used in sweetening mixtures of strong drink, as well as in numberless

articles of cookery. Its abundant introduction into Europe has changed the whole system of cooking and must have largely assisted in rendering food pleasant in an age when the arts of peace have somewhat taken away the violence of appetite which is connected with rude times, and is satisfied more with quantity than quality. For the poor especially is this remarkably true.

A LIST OF SOME OF THE LATER MORE INTERESTING AND CURIOUS INVENTIONS RELATING TO SUGAR, WITH REMARKS:—

1845.—JAMES JOHNSTON patents an ingenious plan of emptying a vacuum pan without destroying the vacuum by a pipe twenty-five feet long. He also has the sugar running down an inclined plane whilst in the vacuum.

FREDRICK GYE presses sugar into suitable forms for use.

1846.—RICHARD WRIGHT patents exposure to hydraulic pressure and steam.

1847.—JAMES JOHNSTON patents polygon shaped sugar moulds, cast-iron crystallizing pots coated with tin, zinc, or enamel. The latter would be good if the enamel did not break off into the sugar.

H. K. CLAYPOLE.—Saving fuel with two generators like locomotive boilers, heated by a fire that first passes over three open boilers. A current of high pressure steam to make a draught. A hot iron tube heated by steam in the clarifying boiler. A canal in the teache for running out sugar. Galvanized iron coolers. These are for the Colonies.

JOHN SCOFFERN.—Combined use of lead and sulphurous acid as separately described.

1848.—J. A. STEINKAMP patents the use of cotton in small pieces of one-eighth to one-fourth of an inch for clearing sugar.

1849.—JOHN OXLAND patents acetate of alumina boiled with sugar at 220° till the acid is removed. The alumina remaining is removed by tannin and a little carbonate of lime.

REECE and PRICE patent hyposulphites with alumina or acetate, hyposulphite of alumina, and various hyposulphites and sulphides of magnesium to precipitate lead. Also hyposulphites and sulphurous acid to remove the sulphide of hydrogen which has been used for removing lead. The bicarbonate of lime for defecation and many other things.

A. V. NEWTON.—Bones dissolved in sulphurous acid for completely extracting the crystallizable sugar. Other antiseptics, as mustard, creosote, horseradish, nitrous acid gas, with or without salts of iron or other salts. Tannin, lampblack saturated with creosote, products of the distillation of certain albuminous matter, tars, wood essence of turpentine, aldehyde, and analogous bodies, chlorine combined with oxygen. Separating ninety-seven per cent. of pure sugar by baryta, and decomposing by carbonic acid or sulphurous. Oxide of strontium, it is said, requires a long time; oxide of lead does it imperfectly. The process gives fifty to sixty parts of hydrate of baryta to one hundred of sugar. Still the sugarate obtained contains fifty per cent. sugar, twenty-two baryta, and twenty-eight water. It is decomposed by a solution of twenty-five quarts of water and twenty-eight pounds of sulphuric acid. It may be

washed till the solution has the strength of 23° to 31° Twaddell. If lime is used, twenty-eight per cent. is taken. The sugarate is filtered out in TAYLOR's filter, or in presses warmed to 100°; it contains five equivalents of base to one of saccharic acid.

The baryta does not offer to be cheaper than animal charcoal, and baryta, at least as a soluble salt, is no less dangerous than lead, whilst it is not so easily detected. Several patents have been taken for removing the baryta, but on this point, the last traces excepted, no difficulty has been found.

C. W. FINZELL—Patent to introduce steam to clear the sieve of the centrifugal machine.

1850.—JOHN SCOFFERN makes a valve of elastic material over a perforated tube.

GEORGE GLYNNE grinds sugar with litharge, and makes a saccharide of lead.

Sugar is a very tender substance chemically. It is easily destroyed. It also readily dissolves many substances. As little of any substance should be added as possible, and as little heat should be given and as little motion.

D. T. SHEARS makes loaf sugar at once on boiling down the juice; purifies sugar by alkaline liquids and sulphurous acid gas; uses also lime and a West Indian plant called *wassama*. Puts a *rouser* in the vacuum pan for stirring round.

HERMAN SCHRODER—a combination of revolving discs on pipes heated by steam to evaporate the sugar.

1851.—R. and J. OXLAND.—When acetate of lime is used, remove by superphosphate of lime or lime. Aluminate of lime to defecate, or phosphate of alumina.

R. A. BROOMAN—Centrifugal apparatus in a vacuum pan; centrifugal drum for evaporation; centrifugal apparatus for cleaning charcoal.

1852.—HENRY BESSEMER.—The claims in this patent being nineteen, are too numerous to mention, and so complicated as to require an article for themselves. It is believed that they rather tend to load a refinery with machinery. Invention will rather simplify the machines, or altogether dispense with some of them; but there are good and ingenious thoughts amongst those of Mr. BESSEMER worth studying, although not as yet found successful.

R. A. BROOMAN.—Endless bands for carrying the sugar to be cleansed.

ROBERT GALLOWAY.—Using plumbite of lime instead of lead.

R. W. LIENIER.—Patent for applying sulphurous acid to the pulp of beet-root or cane before boiling it, adding excess of lime. Use of vessels of wood, slate, stone, glazed metal, or earthenware for boiling juice.

WILLIAM MILLER.—For never allowing the sugar to come in contact with metals; evaporating by surfaces formed of cloth or textile fabric.

BROOMAN.—Removing excess of lime by soap.

GERD JACOB BENSEN.—Hot air passed through the sugar to dry it. Crystallized sugar placed in a vacuum pan. Crystals thus got are mixed with a clear sirup produced from refined sugar; the mixture put into moulds and stored.

In 1852 J. BRANDEIS took a patent for removing lead from sugar by animal charcoal, thus being able to use lead to purify sugar. The Editor believes that the destruction of the animal charcoal soon follows. The oxide of lead, on heating, melts in the pores. This, although possible, would be very expensive.

JOHN ASPINALL proposed lifting the sugar solution in thin layers on an endless band of wire gauze, exposing it to heated air, and drawing off the water. This has not been much used. Even thin layers of sugar may become covered with a pellicle not easily broken. HOWARD's vacuum pan, by keeping up ebullition, allows no hard surface to prevent evaporation. This, however, may be the germ of something good not yet completed.

JAMES HADDEN YOUNG presses sugar between two unyielding surfaces, one of them perforated; he uses a vacuum. The beet-root system is a similar one, but mechanical pressure is used.

HENRY BESSEMER also proposed contact of warm air, raising the sugar in thin layers on screws or discs instead of on wire gauze, as Mr. ASPINALL. He proposed also in his patents to use wooden troughs for crystallizing, and to moisten the crystals with a deliquescent compound of sugar and chloride of sodium, or with gelatine, glucose, or molasses. He adds, also, the use of hot water instead of steam to heat sugar, and warm air below 212°, and tinned vacuum pans. Tin is too easily dissolved. What might be more useful than any of the above is the enamelled vacuum pan, if such large vessels could be covered with enamel.

GEORGE DIXON has a number of perpendicular tubes, in which is placed the sugar and heated by steam; but there is a want of exposure for evaporation. Perpendicular tubes are found to heat the sugar more equally.

JEAN BAPTISTE MOINIER allows the sirup or liquid to fall over spheres, thus obtaining surface, and he allows it to *descend from amongst the spheres*, and exposed to warm air.

1853.—WILLIAM PIDDING patents hydrate of alumina, or silica, or a mixture incorporated with a fatty acid, and adds a little oxide of iron. He seems to wish to include the impurities of the sugar in a kind of fatty salt or soap. This answers for some liquids, but the iron will not improve sugar.

FRANK CLARK HILLS removes the lead from sugar by filtering through sawdust, or by dissolving it out with nitric or acetic acid. Animal charcoal much treated with acid soon loses its texture.

LORD HOWARD DE WALDEN cleanses crystals by hot air and steam. This is, in fact, bleaching with the atmosphere. Air bleaches many substances, but the Editor has not heard if it has been found to act favorably on sugar.

CONRAD W. FINZELL.—Defecation in vacuo. Not yet proved to general satisfaction to be of any benefit.

MANIFOLD, LOWNDES, and JORDAN—Reducing the cane to sawdust, then dissolving the sugar out by steam. This does not seem the right direction, as the great loss is in reality in the juice; it is not left in the cane.

JAMES MAGELSTON—Atmospheric pressure to remove crystals from sugar. This is in fact equal to a vacuum.

ROBERT GALLOWAY—Removing lead by tannic, gallic, and pectic acids, or the soda and potassa compounds.

JOHN and J. E. A. GWYNNE dry beet on an endless band, in one heated cylinder after another.

JOHN THOMAS WAY—Soluble silica to remove the excess of lime in defecation; filtering through a bed of Surrey silica or sand. This would add another operation, as it is supposed it would still require to be passed through the bag filters.

EDWARD BEANS puts the beating tubes into his vacuum pans vertically, and filters through a false bottom covered with sand, powdered flint, or road sweepings.

1854.—CHARLES H. COLLETTE proposed to defecate with lime and superphosphate of lime.

JOSEPH BOUR evaporates by a series of hollow vessels revolving in sirup and internally heated by steam; very much used, especially in the Colonies.

JAMES WRIGHT makes a centrifugal machine, where the outer case revolves with the inner, and a partial vacuum is formed to help the drainage of the liquid without the air-pump.

JOSEPH NASH adds an air-pump to his charcoal filters; fills the centrifugal machine without stopping.

W. A. ARCHIBALD consolidates sugar by exposing to cold air and agitation.

D. T. SHEARS—Another plan for filling and emptying the centrifugal machine without stopping.

PIERRE ANDRÉ DECOSTER has a patent for cutting up the canes; he then presses and mashes by centrifugal power.

L. WRAY wished to take a patent for making sugar from *Holcus saccharatus*, called *impee* on the coast of Africa. Refused.

1855.—R. A. BROOMAN.—A filter of cotton or other fibre between two perforated plates or frames.

JAMES STEELE says that the pin at the apex of the sugar mould is now inserted to make an outlet for the drainage. He inserts it at first, and draws it out when it is desired. A cavity is thus left which assists in drainage. By the insertion of a pin too large a hole is made.

There are many patents for the mode of cutting up sugar into lumps.

JOHN ASPINALL drives the sugar in at the apex of the cone, burning it out at the top.

C. W. FINZELL's patent for the use of NEEDHAM and KITE's apparatus in the filtering of sugar. It is the combination of grooved plates or planks, with filtering cloth, which is laid between two.

ALEXANDER W. ANDERSON precipitates sulphate of copper by tin, and obtains sulphate of tin for sugar refining; then precipitates tin by lime. Removes tin from the sugar at last by animal charcoal.

GARTON and PARSONS.—To treat sugar for distilling they add sulphuric acid, and keep the liquid at 140° for five days, then remove by lime.

STATISTICS OF THE UNITED KINGDOM.—The following, from Messrs. REID's circular, of Liverpool, with alterations, will give some interesting details relating to the United Kingdom:—

Sugar being an article of luxury rather than a necessary of life, the extent of its consumption is affected by the condition of the people as well as by market value, and any increase from the first of these causes is a satisfactory indication of prosperity. Reverting to the early years of the present century, one finds that a long continuation of high prices in addition to periodical privations among the laboring classes gradually reduced the average consumption in the United Kingdom from twenty-two pounds per head in 1801 to sixteen pounds in 1844. A combination of favorable circumstances then arose to cause a reaction; the duties were greatly reduced; production increased; prices ruled low; and an enormous influx of gold commenced pouring into the country, thereby so largely adding to the means of procuring extra comforts and luxuries, that the average consumption per head more than doubled during the last fifteen years.

CONSUMPTION AND IMPORTS.—The following statistical table, made up as far as possible from official returns, will more particularly show the changes which have taken place. The figures for the present year are only approximate, as the return had not been made out when the tables were calculated. The prices and duties quoted are for West Indian Muscovado:—

Years.	Population of United Kingdom.	Consumption of Sugar.		Prices and Rates of Duty.			Duties paid on all Descriptions.	Per Head.
		Total Tons.	Lbs. per Head.	Gazette Average Price.	Rate of Duty.	Total per Cwt.

	272,974	33,677,061

This has much increased. Louisiana produced in 1858 three hundred and sixty-two thousand two hundred and ninety-six hogsheads, at sixty-nine shillings per hogshead, and value of twenty-four millions, nine

hundred and ninety-eight thousand, four hundred and twenty-four dollars. A hogshead is half a ton. Total Maple sugar produced in 1859 is believed to be twenty-seven thousand tons, or sixty millions four hundred and eighty thousand pounds.

The annexed extracts from the commercial review of Messrs. DE CONINCK, Brothers, and Company, furnish some interesting particulars of the statistical position of sugar in France.

The importation of foreign sugar into that country rose in 1859 to eighty-two thousand tons against forty-five thousand tons in 1858, and sixty-five thousand tons in 1857.

From the Colonies, France received last year five thousand tons more than in 1858; while the manufacture of indigenous or beet-root sugar produced in the season 1858-9, was one hundred and thirty-two thousand tons, being twelve thousand tons in excess of the first estimates. During the last six years, the quantities received by France from her Colonies were as follows:—

113,000 tons in 1859	95,400 tons in 1856
108,000 tons in 1858	89,000 tons in 1855
92,100 tons in 1857	82,000 tons in 1854
99,500 tons in 1847.	

The sources of these supplies are subjoined:—

QUANTITIES STATED IN TONS OF 1000 KILOGRAMMES.

	Guadeloupe.	Martinique.	Reunion.	Cayenne, &c.	Total.
1859 ..	24,400 ..	27,900 ..	58,600 ..	1100 ..	113,000
1858 ..	29,500 ..	27,400 ..	52,000 ..	— ..	108,000
1857 ..	18,500 ..	22,300 ..	51,000 ..	300 ..	92,100
1856 ..	21,600 ..	26,600 ..	57,000 ..	200 ..	95,400
1855 ..	21,000 ..	18,500 ..	49,900 ..	600 ..	89,000
1854 ..	22,001 ..	24,300 ..	35,700 ..	— ..	82,000

The consumption of sugar in France in 1859 is thus estimated:—

	Tons.
Sugar—Indigenous.....	120,000
" From French Colonies.....	95,000
" " "	60,000
Total.....	275,000
Deduct export of refined sugar.....	52,000
Remains for consumption in France.....	223,000

The season of 1858-59 produced of indigenous sugar—

132,600 tons against 156,000 tons {1857-58
1856-57
1855-56

It is not thought that the quantity produced in the season 1859-60 will exceed that of the preceding one, *videlicet*, one hundred and thirty-two thousand tons.

ZOLLVEREIN CUSTOMS RECEIPTS ANNUALLY FROM 1834 TO 1857, BOTH INCLUSIVE.

Years.	Total population of the States of the Zollverein.	Gross receipts in account of export, import, and transit duties.	Average sum per head of the population, derived from custom dues, <i>et cetera</i> , tax on beet-root.
		Rix-dol.	Groschen. Pf.

1857 ..	32,940,780	26,595,788	29 5

The duty is now seven and a half groschen for one hundred pounds, and brings nearly three shillings per head.

AMOUNT OF RAW BEET-ROOT USED FOR THE PRODUCTION OF SUGAR, AND AMOUNT OF DUTY RECEIVED IN THE STATES OF THE ZOLLVEREIN.

Years.	Amount of beet-root used for sugar. Cwt.	Produce of the tax in rix-dol.
1842 to 1847	4,322,712	232,991
1847 to 1853	13,998,570	1,156,744
1853 to 1856	19,832,679	3,966,536
1856 to 1857	27,551,207	5,312,856
1857 to 1858	28,915,133	5,783,033

CONSUMPTION OF BEET-ROOT SUGAR IN THE STATES OF THE ZOLLVEREIN.

Years.	Consumption of colonial sugar. Zollverein cwt.	Consumption of beet sugar. Zollverein cwt.	Total consumption of sugar. Zollverein cwt.
1844 to 1846 ..	1,278,421	264,283	1,542,704
1847 to 1849 ..	1,154,005	646,650	1,800,655
1850 to 1852 ..	739,958	1,219,718	1,959,676
1853 to 1855 ..	654,386	1,487,452	2,141,838

In 1856-57 there were two hundred and thirty-three manufacturers of beet-root sugar in the Zollverein. In 1839-40, four and four-fifths pounds per head was consumed; in 1853-55 there were six and a quarter pounds consumed.

The shipments of beet-root sugar, according to BARUCHSON and Company of Douai, to Great Britain, were little more in 1858-59 than half those of the preceding season, owing to the prices in England being at several periods below those of France. They consist as follows:—

FROM 1ST NOVEMBER, 1858, TO 31ST OCTOBER, 1859.

To Liverpool	about 3218 tons.
To the Clyde	" 2240 "
To London	" 1614 "
To West of England	" 1234 "
To Hull	" 37 "

Total..... " 8343 "

A good deal of this was re-exported, as it could not compete with Colonial.

PRICES CURRENT.

Low brown, equal to No. 7 to 8 Dutch standard—very scarce	21s 0d to 22s 6d
Light brown, equal to No. 10 to 10½ Dutch standard	23s 6d to 24s 0d
Grey and yellow, equal to No. 12 Dutch standard	25s 0d to 25s 6d
Per cwt., cost, freight and insurance to cover average.	

In Russia the consumption has nearly doubled within a few years; but even now it is only two pounds per head.

DR. ANGUS SMITH of Manchester kindly rendered his valuable aid during the progress of this article, and for which the Editor is indebted to him.

SULPHUR—*soufre*, French; *schwefel*, German—is one of the elements of modern chemists, and was a still more important one in the theory of the alchemists.

OCCURRENCE.—It is found in nature, both in a free state and in combination with metals, as sulphides and sulphates. In the free state it occurs in volcanic regions, large quantities being imported to this country from Sicily. The native sulphur occurs both amorphous and crystallized. In the latter state it usually occurs in right rhombic octohedra, although it does not assume this shape under all conditions; it crystallizes in many

forms, almost as varied as the methods of procuring the body in the crystallized state. Native sulphur is far from being pure, containing a considerable quantity of adhering soil and other matter from which it is purified by different methods dependent on the purposes to which it is to be applied. Large quantities of sulphur exist in combination with metals as sulphides; of these may be mentioned the sulphides of copper, lead, iron, and zinc; these bodies, in fact, forming the ordinary ores or minerals of these metals, from which the sulphur has to be burnt off before the metal itself can be obtained. Sulphur occurs also in nature in saline combinations as sulphates of the alkalis and earths; for instance, the sulphate of soda and potassa, which are comparatively rare, and the sulphates of baryta and lime, which occur in immense quantities.

PROPERTIES.—Sulphur is a pale yellow, solid, very

brittle, becoming negatively electrical by heat or friction; it was at one time, in an earlier period of electrical history, used, when formed into globes and mounted as glass cylinders and plates are at the present day, as a source of electricity. Its specific gravity is variously stated, but most writers agree in considering it as 1.98—probably its density is dependent on the degree or stage of heat to which it has been carried while in a fused state. It is perfectly inodorous unless when rubbed, when a peculiar smell is developed. This was once supposed to arise from a hydrogen compound formed by friction; it is now ascribed rather to the production of ozone. Owing to its brittleness, as well as from conducting heat badly, it soon splits into innumerable cracks when held in the warm hand; by inclosing a stick of cast sulphur in the hand, and holding it close to the ear, this is easily detected, a continued series of very slight cracklings are heard similar to the cracklings of an electric machine when in work, only much fainter. Sulphur, though perfectly insoluble in water, is soluble in a variety of liquids, most of which are capable of dissolving a greater quantity of the body when hot than they are when cold, in consequence of which they, on cooling, deposit this excess in the shape of crystals. Oil of turpentine is capable of dissolving a considerable quantity. In fact, it has been proposed to take advantage of this property in the analysis of gunpowder; for by heating this body with turpentine in a warm state, having previously dissolved out the nitrate of potassa with water, we can dissolve out the sulphur, leaving the charcoal, which is not soluble in this menstruum, behind. Bisulphide of carbon will also dissolve a considerable quantity of sulphur, which can be again obtained in crystals by allowing the solvent to evaporate gradually. Fat oils are also capable of dissolving it. A compound called *oleum sulphuratum*, or balsam of sulphur, once figured in the Pharmacopœia of the London College, though now omitted. This was formed by dissolving sulphur in olive oil, employing a tolerably high temperature to effect the combination. Ether, petroleum, and fused paraffine, may be mentioned as solvents of sulphur.

Pure sulphur exhibits some curious phenomena in connection with heat. Although perfectly solid at the ordinary temperature, it fuses at a heat little more than that of boiling water, and at a higher heat passes through various physical changes; and finally, on raising the temperature still higher, it volatilizes completely, without leaving anything behind. The following experiment is interesting, as displaying some of the peculiarities of this body:—Procure a small saucepan, and partly fill it with fragments of sulphur; place this over a gentle fire, having first put on the lid; after a while it will fuse. This takes place at a temperature of about 228°, forming a thin brownish-yellow transparent liquid. On heating still higher a very perceptible change takes place; the sulphur, instead of remaining in the very liquid state, becomes of a thick consistence, so much so that the vessel containing it may be completely inverted without fear of loss. This occurs at a temperature of between 428° and 482°. At a still higher degree the action is reversed, the melted sulphur becomes thinner and thinner until it reaches the boiling point,

when it begins to pass off as vapor. Other phenomena may be noticed by interrupting the experiment at various stages; for instance, if it be wished to obtain crystals of sulphur, it is only necessary to take the sulphur while in the first liquid stage, to pour this into a basin or other vessel with sloping sides, and there allow it to stand. In a few minutes after the top portion has solidified and formed a crust, break two holes through this crust at opposite sides of the vessel. If the basin be now inverted partially, the sulphur, which still remains in the liquid state in the interior, will run out of one hole while air rushes through the other. Let the vessel stand until cold, carefully detach the solidified mass from the containing vessel, and by means of a saw divide it into two halves. These will be found to be full of beautiful crystals of sulphur. It is possible that the first experiment may not be very successful, but a few trials will enable the operator to procure a mass of crystals, radiating into, and interlacing each other in every direction from the external crust. If the sulphur, immediately after passing, or perhaps better, while scarcely through the thick stage, be poured into water, it does not solidify and assume the ordinary yellow brittle appearance which it would do were it so treated while in the first liquid state; instead of doing so it remains in this plastic condition even when cold, bearing a stronger resemblance to caoutchouc than sulphur. In this state it is perfectly elastic, may be pulled out to a considerable length without breaking, and, in fact, does not in the remotest degree resemble sulphur. But for its color, it might be mistaken for wheat gluten, possessing the same soft elasticity as that body. It will remain in this state for some time, not resuming its ordinary aspect until after the lapse of some days.
